Despite the rarity of appendiceal tumors, their incidence is rising, estimated to approach 1 per 100,000.[15] Commonly, these are initially diagnosed via an appendectomy for appendicitis or found incidentally on imaging. Carcinoid tumors represent nearly half of the malignant lesions of the appendix but are less commonly encountered with peritoneal metastases. The Peritoneal Surface Oncology Group International (PSOGI) supports World Health Organization (WHO) nomenclature that has been widely accepted for primary appendiceal neoplasms: low-grade appendiceal mucinous neoplasm (LAMN), high-grade appendiceal mucinous neoplasm (HAMN), and mucinous adenocarcinoma with or without signet ring cells.[16]

Pseudomyxoma peritonei is a clinical syndrome of mucinous ascites that describes accumulation of mucin. Pseudomyxoma can be associated with or without epithelial cells in the mucin and is nearly always a result of peritoneal dissemination after appendiceal tumor rupture (Fig. 70.4). Carr et al. described diagnostic criteria for intraabdominal mucin to assist in the characterization of pseudomyxoma peritonei that range from acellular mucin, low-grade mucinous carcinoma peritonei or disseminated peritoneal adenomucinosis (DPAM) to high-grade mucinous carcinoma peritonei or peritoneal mucinous carcinomatosis (PMCA) with or without signet ring cells.

The systemic treatment of appendiceal cancer has been historically extrapolated from the treatment of colorectal cancer despite strong evidence that these represent genetically different entities.[17,18] In the past four decades, there has been a significant accumulation of experience in the treatment of these tumors. CRS and HIPEC have been established as an effective modality in the treatment of these tumors with a track record for safety and efficacy.[19,20] In the only completed randomized clinical trial for treatment of appendiceal tumors to date, Levine et al. studied the difference in hematologic toxicities with mitomycin C versus oxaliplatin and found similar overall and progression-free survival (PFS); however, there was more leukopenia and a slightly worse short-term quality-of-life score in the mitomycin arm.[21]

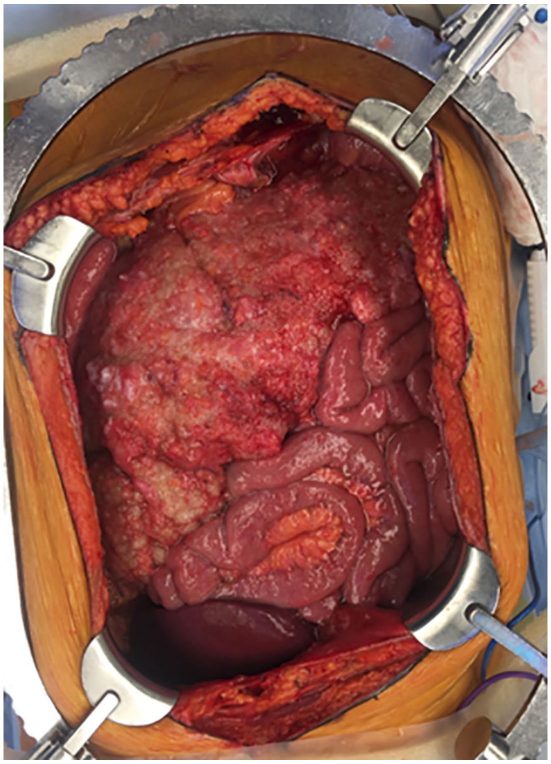

FIGURE 70.4 Omental "cake" obscuring complete Peritoneal Carcinomatosis Index evaluation from low-grade appendiceal neoplasm with relative small bowel sparing. (Visualized through a midline laparotomy incision.)

Modern systemic chemotherapy has been used primarily for patients who are not surgical candidates and is most efficacious for high-grade carcinoma.[22] The role of perioperative chemotherapy is still unclear in appendiceal neoplasms, with some studies even reporting a detrimental impact on survival after preoperative chemotherapy.[23,24] For low-grade disease, a recent randomized crossover trial showed no benefit of 6 months of fluoropyrimidine-based systemic chemotherapy compared with observation.[25] This builds on a body of literature, primarily retrospective studies, that has established CRS and HIPEC as the primary modality of treatment, with little role for systemic chemotherapy.[26,27]

Appendiceal Tumors Ex Goblet Cell

Ex goblet cell appendiceal tumors, also called *goblet cell carcinoid* or *adenocarcinoid,* demonstrate mixed pathologic features of a neuroendocrine tumor and adenocarcinoma at the same time. These tumors demonstrate significant heterogeneity, and the Tang classification has been used to differentiate them pathologically as well as predict outcomes.[28] Typical goblet cell carcinoids were categorized in group A, whereas group B was classified as adenocarcinoma ex goblet cell with signet ring features, and group C included poorly differentiated adenocarcinomas. Localized tumors are typically treated with right hemicolectomy, particularly in the setting of goblet cell adenocarcinoma, whereas stage IV patients with peritoneal dissemination are considered for CRS with HIPEC.[29,30]

Mesothelioma

Peritoneal mesothelioma is a very rare subtype of intraabdominal cancer that occurs from the malignant transformation of mesothelial cells. A recent Surveillance, Epidemiology, and End Results (SEER) database analysis estimated the incidence to be around 1 case per million person-years,[31] or only 300 to 400 cases annually in the United States. Despite its rarity, it is further subdivided into histopathologic subtypes: epithelioid (the most common), sarcomatoid (the rarest), and a mixed subtype sharing features of both called *biphasic*. Given the low incidence, there is a paucity of dedicated clinical trials, and systemic treatment is extrapolated from pleural mesothelioma, which is nearly 10 times as prevalent. Diagnosis can be challenging, and percutaneous biopsies can frequently be nondiagnostic or nonspecific. Cytologic examination of ascites is rarely diagnostic. Diagnostic laparoscopy with peritoneal biopsies is often necessary to establish the diagnosis definitively and obtain adequate tissue sample. The treatment of the epithelioid and highly select biphasic cases is primarily CRS and HIPEC in centers experienced with this disease.[32–34]

Various chemotherapeutic agents have been used for IP perfusion, with the backbone being a platinum agent such as cisplatin or carboplatin. Sarcomatoid peritoneal mesothelioma cases are best treated nonoperatively, with systemic chemotherapy alone. The first-line systemic treatment is nivolumab and ipilimumab, extrapolated from the CheckMate 743 trial, which demonstrated improved overall survival (OS) compared with platinum-based chemotherapy and pemetrexed (former standard of care).[35] Cisplatin and pemetrexed with or without bevacizumab are still used for unresectable disease. A recent phase II trial showed a 40% objective response rate with atezolizumab and bevacizumab after progression on platinum-pemetrexed chemotherapy in a prospective cohort of 20 patients.[36]

Well-differentiated Papillary/benign Cystic Peritoneal Mesothelioma

Benign and preinvasive mesothelial tumors are very rare and pose a challenge in management because of very limited data, mainly from small case series or case reports (Fig. 70.5). Benign cystic peritoneal mesotheliomas, previously called *peritoneal inclusions cysts,* are primarily diagnosed in females of childbearing age and tend to cluster in the pelvis. The moniker *benign* can be misleading because these lesions can be progressive. The primary treatment is surgical resection and CRS with hyperthermic IP chemotherapy, which has been reported to decrease recurrences.[37] However, we reserve surgery for patients with proven progressive disease for these subtypes. After surgery, recurrences are common, and surgical resection is typically recommended for worsening symptomatic disease.

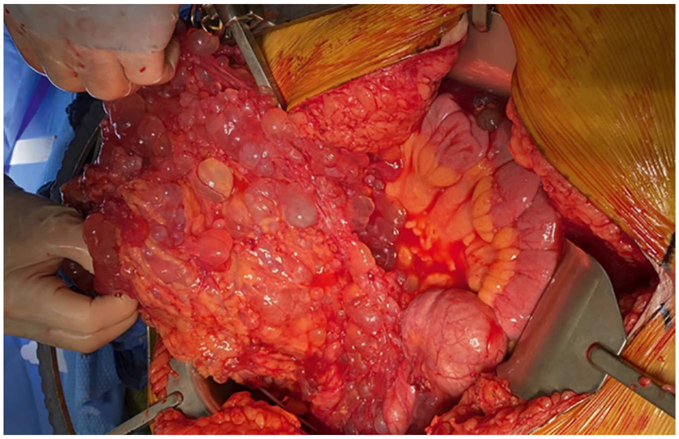

FIGURE 70.5 Cystic mesothelioma, greater omentum, with substantial tumor burden displayed via midline laparotomy.

Colorectal Cancer

Colorectal cancer remains the third most common cancer in the United States in both males and females. Peritoneal dissemination is found in approximately 10% of cases and is the second most common cause of death attributable to colorectal cancer, after liver metastases. Because of significant challenges in the diagnosis and treatment, patients with peritoneal carcinomatosis have a poorer prognosis compared with liver or lung metastases.[38] The development of CRS and HIPEC has opened new possibilities in a disease that was previously viewed with nihilism. Laparoscopic evaluation before CRS is a useful tool for selecting patients for CRS. We use a laparoscopic PCI score >20 as a contraindication for CRS and HIPEC.

Several large retrospective studies have been published documenting the role of CRS + HIPEC in carefully selected patients who can achieve complete cytoreduction.[39] The first randomized clinical trial was from the Netherlands, and despite criticisms regarding the design, type of chemotherapy used, and inclusion of patients with appendiceal cancer, it paved the way for additional trials. Remarkably, it found a near doubling of survival in patients undergoing CRS and HIPEC compared with systemic therapy. It included patients with peritoneal carcinomatosis and reported improved survival after CRS and HIPEC with mitomycin C compared with systemic therapy with or without palliative surgery.[40] More recently, the French randomized controlled trial PRODIGE 7 compared CRS and HIPEC versus CRS alone with modern systemic chemotherapy. Even though there was no OS benefit associated with HIPEC, the results published represent significant improvement compared with historical results, with a median OS of 41 months in both arms and 5-year survival of 39.4% versus 36.7% in the HIPEC versus CRS-alone arm.[41] This study has been strongly criticized for using a brief 30-minute oxaliplatin perfusion as the HIPEC agent. Nevertheless, it clearly demonstrated that CRS should be the standard of care in resectable cases of peritoneal dissemination because it reported the best outcomes ever for patients in this setting.

Earlier diagnosis has been a challenge for peritoneal carcinomatosis. Therefore, several groups have assessed the role of second-look operations or adjuvant HIPEC in preventing peritoneal recurrence in high-risk patients. The results to date have been mixed. A Spanish phase III trial reported significantly improved locoregional recurrence rates after cytoreduction and HIPEC (1 hour of mitomycin C at 30 mg/M^2) versus cytoreduction alone in a group of patients with T4 tumors and no carcinomatosis.[42]

A similar Dutch trial (COLOPEC) did not show improvement in peritoneal metastasis-free survival with prophylactic HIPEC for perforated or T4 colorectal cancers, albeit using an attenuated chemoperfusion of oxaliplatin for 30 minutes.[43] A French phase III trial assessed the role of systematic second-look surgery and HIPEC in patients with high-risk tumors or completely resected peritoneal or ovarian metastases, concluding that there was no disease-free survival benefit with the addition of HIPEC (oxaliplatin for 30 minutes).[44] In light of the current evidence, adjuvant or “prophylactic” HIPEC is considered investigational and should be performed in the setting of a trial, although the Spanish T4 trial is suggestive of a modest benefit. Clearly, there is a pressing need for more sensitive modalities to achieve early diagnosis of peritoneal recurrences.

A significant proportion of patients with peritoneal carcinomatosis are also diagnosed with liver or lung metastases. In an analysis of phase III trial data, only 2% of patients were found to have isolated peritoneal metastases, whereas 11% were found to have other metastatic sites besides peritoneal.[38] The optimal timing and chemotherapy regimen for the management of peritoneal metastases remains under investigation. A recent phase II trial showed radiologic responses in 28%, and pathologic responses in 38%, of patients who underwent CRS and HIPEC after 3 months of chemotherapy (FOLFOX/CapeOx/FOLFIRI).[45] Even though liver metastases do not represent an absolute contraindication for cytoreduction and HIPEC, the timing and selection of patients need to be done in a multidisciplinary setting and by experienced teams. In a multi-institutional analysis, excellent outcomes were reported from CRS/HIPEC and liver resection, whether simultaneous or in a two-stage approach. Median OS was 47.6 months, severe morbidity was 32.3%, and perioperative mortality was 4%.[46]

Ovarian Cancer

Epithelial ovarian cancer is the leading cause of death from gynecologic cancer in the United States. Peritoneal dissemination is very common, and optimal cytoreduction followed by adjuvant chemotherapy has been the standard of care for many years. Several phase III randomized clinical trials and pooled analyses have demonstrated the efficacy of IP chemotherapy and demonstrated improved PFS and even OS compared with IV chemotherapy alone.[47–49] However, these results have been criticized because of increased rates of hematologic toxicities, renal toxicity, and difficulty in tolerating all intended treatment cycles. A trial that compared IV carboplatin/paclitaxel versus IP carboplatin/IV paclitaxel and IP cisplatin/IP paclitaxel (all arms included bevacizumab) showed no difference in PFS between IV and IP chemotherapy arms.[50]

The management of these patients with neoadjuvant chemotherapy followed by interval debulking is being more commonly used. This approach is particularly helpful in patients with a high volume of disease upon presentation and other significant comorbidities precluding them from upfront debulking. In a recent analysis of long-term survival data from the Ovarian Cancer Hyperthermic Intraperitoneal Chemotherapy-1 (OVHIPEC-1) trial, the addition of HIPEC to interval debulking led to improved survival outcomes compared with interval debulking alone, with median OS of 44.9 versus 33.3 months.[51] The management of these patients is complex and individualized; even though IP chemotherapy is an acceptable addition to optimal debulking, its role in ovarian cancer is not typically as a first-line therapy for all patients with advanced disease.

Gastric Cancer

Even though gastric cancer is less common in Western Europe and the United States, it remains a significant global health problem, particularly in Asia. Gastric cancer has a clear propensity for metastases to the peritoneal cavity. All patients with suspected locoregional disease should be considered for diagnostic laparoscopy with biopsy of suspicious lesions and peritoneal washings.[52] Positive peritoneal cytology is considered M1 disease, and systemic therapy remains the first-line standard of care. However, survival outcomes have been dismal, with median OS of less than 12 months for patients with peritoneal disease resulting from gastric cancer. Several studies, primarily from Asia, have investigated the role of CRS and IP chemotherapy in gastric cancer. The PHOENIX-GC trial was a phase III randomized clinical trial that compared IP paclitaxel and IV paclitaxel versus IV S-1 plus cisplatin on a two-to-one ratio. Even though the trial did not meet its primary end point of median survival, there was a trend toward improved survival with the IP paclitaxel of 17.7 versus 15.2 months and improvement in baseline ascites.[53] In a Chinese phase III trial, patients with gastric cancer and synchronous peritoneal metastases were randomized to CRS versus CRS and HIPEC with cisplatin and mitomycin C. Median survival was improved in the HIPEC arm at 11 months versus 6.5 months in the CRS-alone arm.

Primarily retrospective studies and small randomized trials have been conducted in the Western Hemisphere to assess the role of CRS + HIPEC. The Gastrectomy With Metastasectomy Plus Systemic Chemotherapy (GYMSSA) trial randomized patients to CRS, HIPEC, and systemic therapy versus systemic therapy alone. All patients in the experimental arm had a complete cytoreduction, and median survival was 11.3 months versus 4.3 months in the systemic therapy arm.[54] More recently, the German GASTRIPEC trial compared CRS alone with CRS + HIPEC using mitomycin C and cisplatin with standard perioperative chemotherapy in both arms. The study was closed because of slow accrual, and median survival was the same in both arms at 13.9 months. However, PFS doubled in the CRS + HIPEC arm to 7.1 months from 3.5 months, and distant metastases–free survival increased as well.[55] In summary, CRS and HIPEC should be considered for patients with limited peritoneal disease (we suggest a PCI <6) after a good response to systemic therapy, particularly in the setting of a trial.

The role of palliative gastrectomy in patients with limited metastatic disease was investigated in the REGATTA trial. Patients were randomized to gastrectomy followed by systemic therapy versus systemic therapy alone, and at 2 years, OS was 25.1% versus 31.7%, respectively. The study was closed early as a result of futility and because patients who had total gastrectomy could not tolerate oral S-1.[56] The group from MD Anderson has published encouraging results from using repeated laparoscopic HIPEC with and without cytoreduction in a group of patients with gastric cancer and peritoneal metastases after maximal treatment with systemic therapy.[57,58]

An area of active research is the use of adjuvant or “prophylactic” HIPEC in patients with high-risk gastric cancer. The interim safety results of the European Gastric Cancer Hyperthermic Intraperitoneal Chemotherapy (GASTRICHIP) trial showed no difference in morbidity after perfusion with oxaliplatin over 30 minutes in combination with IV 5-fluorouracil (5-FU) leucovorin.[59] A Japanese trial is investigating the role of prophylactic HIPEC using IP paclitaxel and the role of the same regimen to clear cytology-positive disease without gross peritoneal metastases.[60] Several questions remain in the treatment of peritoneal carcinomatosis resulting from gastric cancer, and despite the scarcity of level 1 data, there is a growing body of evidence demonstrating efficacy of IP chemotherapy for select patients with limited disease and after response to systemic therapy.

FUTURE DIRECTIONS

Four decades into the development of CRS and HIPEC in the treatment of peritoneal malignancies, there are still unanswered questions. It must be kept in mind that CRS with compete resection of apparent disease is the cornerstone of therapy for patients with peritoneal metastasis. Further, it must be emphasized that HIPEC is a treatment platform for drug delivery. As such, it will be modified in regard to agents, pressurized delivery, duration, and temperature with ongoing research. For many types of peritoneal metastasis, CRS and HIPEC should be applied with systemic therapies, not in lieu of them.

Incremental progress has been made with improvement of survival from peritoneal metastases associated with several primary cancers. There is a need for more multi-institutional collaboration and cooperative trials to move the field forward. New technologies, such as circulating tumor cells and circulating tumor DNA, offer new ways to evaluate and monitor for recurrence.[34,61] Further, the development of patient-derived organoids provides a new high-throughput platform to investigate tumor susceptibility to different chemotherapeutic agents and represents a new frontier in personalized medicine.[62,63] Treatment of peritoneal metastasis has moved from therapeutic nihilism to mainstream therapy, offering selected patients the real possibility of long-term survival with excellent quality of life.

  Bullet Points

INTRODUCTION

Lymphadenopathy remains a common clinical condition that affects patients of all age groups. It refers to the swelling of lymph nodes, which can occur in isolation or could be more generalized on presentation. When initially discovered, lymphadenopathy can pose a diagnostic dilemma because the underlying etiology is broad and includes malignancies, infection, autoimmune disorders, medications, and iatrogenic causes. For surgeons, patients with new lymphadenopathy remain a common clinical scenario. The critical task in approaching these patients is determining whether their presentation is associated with a benign self-limited process versus a malignancy or other serious condition requiring immediate attention. As a result, establishing a systematic approach for surgeons remains paramount when evaluating lymphadenopathy cases to ensure the workup remains safe and effective and avoids the potential for unnecessary procedures. This chapter reviews the evaluation of patients with lymphadenopathy, with particular emphasis on differential diagnoses, diagnostic imaging, biopsy techniques, pathology, and clinical management.

DIAGNOSTIC CONSIDERATIONS

Given the numerous causes that can lead to lymphadenopathy, the initial diagnostic considerations should include the patient's age, lymph node location (isolated vs. generalized), duration of lymphadenopathy, antecedent events (recent infections, new medications/immunizations), extranodal signs and symptoms, and physical examination findings. A thorough initial assessment will often assist in refining the diagnostic evaluation (Fig. 71.1).

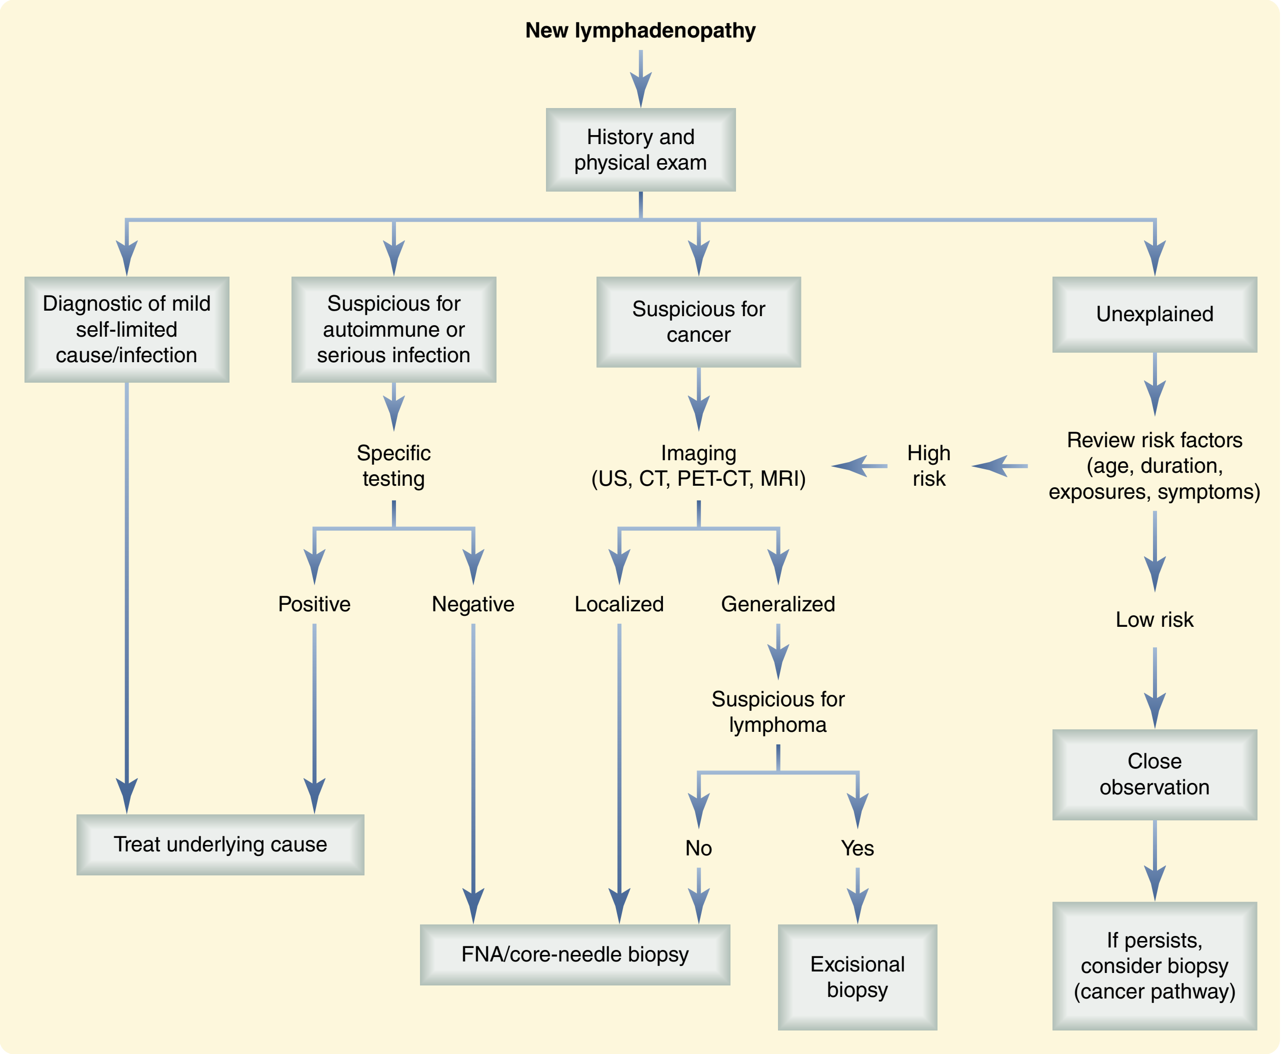
Among the pediatric population, lymphadenopathy is common, with up to 50% of children developing a palpable lymph node at any one time.[1] For the vast majority of children, lymphadenopathy reflects a benign reactive process secondary to a self-limiting infection. Lymphadenopathy due to a neoplastic process is extremely rare among younger patients, with only 0.4% of unexplained lymphadenopathy cases being attributable to cancer among individuals less than 40 years of age.[2] Conversely, in older adults, new lymphadenopathy can be a more worrisome finding, with a greater percentage of cases (4%) due to malignancy.

The ascertainment of recent exposures and past medical history is also a critical component in the evaluation of patients with lymphadenopathy. Obtaining a thorough history that includes prior cancers, recent infections, travel, medications, recent immunizations, and sexual history can aid in the diagnostic workup. Additionally, certain symptoms may help narrow the diagnosis. Fevers, although nonspecific, could suggest either an infectious or malignant cause. However, the presence of constitutional "type B" symptoms that include fever, night sweats, and unintentional weight loss may suggest an underlying lymphoproliferative disorder. As for an autoimmune process, extranodal signs and symptoms such as arthralgias, muscle weakness, and skin rash could also accompany the lymphadenopathy.

The duration of the lymphadenopathy can also assist in the diagnostic assessment. For lymphadenopathy that lasts less than 2 weeks or lasts longer than 12 months without a change in size, or if the patient reports a fluctuation in lymph node size, the likelihood of it being caused by a malignant process is extremely low.[3]

PHYSICAL EXAMINATION

Patients evaluated for new lymphadenopathy should undergo a thorough lymphatic examination (cervical, axillary, inguinal, epitrochlear, popliteal) that takes into consideration common lymphatic drainage patterns (Table 71.1). Determining whether the lymphadenopathy is isolated or generalized will further refine the examination and help assist in determining whether additional ancillary diagnostic tests (blood work, imaging) are necessary. The



New lymphadenopathy
History and physical exam
Diagnostic of mild self-limited cause/infection
Suspicious for autoimmune or serious infection
Suspicious for cancer
Unexplained
Specific testing
Imaging (US, CT, PET-CT, MRI)
High risk
Review risk factors (age, duration, exposures, symptoms)
Positive
Negative
Localized
Generalized
Low risk
Suspicious for lymphoma
Close observation
No
Yes
Treat underlying cause
FNA/core-needle biopsy
Excisional biopsy
If persists, consider biopsy (cancer pathway)

TABLE 71.1 Peripheral Lymph Node Basins: Location, Drainage Pattern, Differential Diagnosis

LOCATION	DRAINAGE PATTERN	DIFFERENTIAL DIAGNOSIS
Submandibular/ Submental	Lower face, mouth, lips, tongue, salivary glands	Infection, mononucleosis, lymphoma, head and neck cancer, melanoma or other cutaneous skin cancers
Cervical	Scalp, neck, upper back, thorax	Infection, mononucleosis, lymphoma, head and neck cancer, melanoma or other cutaneous skin cancers
Supraclavicular	Mediastinum, lungs, esophagus, thorax, abdomen/ retroperitoneum (via thoracic duct)	Infection (bacterial/fungal); lung/thoracic, esophageal, retroperitoneal, or GI cancer; lymphoma; melanoma or other cutaneous skin cancers
Axillary	Upper extremity, thoracic wall, breast	Infection, lymphoma, breast cancer, skin cancer (melanoma, cutaneous squamous cell carcinoma)
Epitrochlear	Forearm, hand	Infection, lymphoma, sarcoidosis, melanoma or other cutaneous skin cancers
Inguinal	Lower extremities, penis, scrotum, vulva, vagina, perineum, gluteal region, lower abdominal wall, anus	Infections of the lower extremities or abdominal wall, sexually transmitted infections, lymphoma, melanoma or other cutaneous skin cancers, GU/GI/GYN malignancy
Popliteal	Lower leg, sole of foot	Infections of the lower extremity, melanoma or other cutaneous skin cancers

GI, Gastrointestinal; *GU,* genitourinary; *GYN,* gynecologic.

quality of the enlarged lymph nodes should also be assessed. Lymph node qualities can include size, tenderness, warmth, consistency (firm vs. fluctuant), and fixed versus mobile. Tender lymph nodes often reflect an inflammatory or reactive process caused by an infection but can also be seen with aggressive malignancies that result in rapid enlargement of the lymph node, resulting in hemorrhage or necrosis.[4] As a result, the qualitative characteristics of lymphadenopathy are usually inadequate in differentiating benign versus malignant causes. Additional examination findings, although infrequent, could include concomitant splenomegaly, which occurs with infectious mononucleosis and lymphoproliferative processes (lymphoma, leukemia) (Table 71.1).

DIFFERENTIAL DIAGNOSIS AND PATHOLOGIC EVALUATION OF LYMPHADENOPATHY

The differential diagnosis for lymphadenopathy can be broadly categorized into infectious, noninfectious benign, and malignant etiologies (Table 71.2).[4,5] Pathologic evaluation is critical in arriving at a diagnosis for otherwise unexplained lymphadenopathy.

Infectious Lymphadenopathy: Bacterial

Bacterial infections can cause regional lymphadenopathy and lead to acute lymphadenitis.[6] These are often due to soft tissue infections caused by *Staphylococcus aureus* or group A streptococcus. In the early acute phase, there is an increase in eosinophilic proteinaceous material and neutrophils and macrophages. Sometimes bacteria can be seen on histology, and a tissue Gram stain may be a useful tool.[5] Definitive diagnosis requires culture of infected tissue.

TABLE 71.2 Differential Diagnosis of Lymphadenopathy

INFECTIOUS	NONINFECTIOUS BENIGN	MALIGNANT
Bacterial: • Soft tissue infections • Tuberculosis • Cat-scratch disease • Syphilis	Reactive nonspecific changes: • Reactive follicular hyperplasia • Reactive paracortical hyperplasia	Hodgkin lymphoma: • Nodular lymphocyte-predominant • Classic type
Fungal: • Coccidioidomycosis • Histoplasmosis • Cryptococcosis	Autoimmune-associated lymphadenopathies: • Rheumatoid arthritis • Systemic lupus erythematosus	Non-Hodgkin lymphoma: • Lymphoblastic leukemia/ lymphoma • Mature B-cell lymphoma • Mature T-cell lymphoma
Viral: • Epstein-Barr virus • Human immunodeficiency virus • Cytomegalovirus • Herpes simplex virus	Reactive lymphadenopathies: • Rosai-Dorfman • Kimura disease • Castleman disease • Sarcoidosis	Tumor metastases: • Breast • Melanoma • Head and neck • Other

Mycobacterium tuberculosis lymphadenitis is the most common extrapulmonary manifestation of tuberculosis. This usually presents as painless lymphadenopathy involving the cervical lymph nodes.[5,7] Necrotizing granulomatous inflammation and caseous necrosis can be seen histologically. *M. tuberculosis* can be identified by acid-fast stains and appears as bright-red bacilli. Atypical mycobacteria, such as *M. marinum, M. kansaii,* and *M. avium-intracellulare,* can cause lymphadenitis in immunocompromised patients, such as those with human immunodeficiency virus or hairy cell leukemia. A histologic hallmark of atypical mycobacterial lymphadenitis is the concomitant existence of suppurative and nonnecrotizing granulomatous inflammation. Acid-fast bacilli can also be identified on histology.[8]

Bartonella henselae is the pathogenic organism responsible for cat-scratch lymphadenitis. The associated lymphadenopathy is usually unilateral and appears 1 to 3 weeks after a cat-inflicted injury, with accompanying fever and fatigue in some cases. *B. henselae* can be visualized within the lymph node using the Warthin-Starry silver stain[9] and is associated with an increase in macrophages and small areas of necrosis.[5]

Treponema pallidum infection can lead to syphilitic lymphadenitis during any of the three stages of disease.[5] During the primary syphilis stage, inguinal lymph nodes are most commonly affected in the regional area of primary infection. Cervical lymphadenopathy is the second most common site. Generalized lymphadenopathy can occur in the secondary syphilis stage 6 to 8 weeks after initial onset of infection and can involve the femoral, cervical, and axillary lymph node basins. Laboratory screening tests can be used as a first step, but confirmatory tests specific for *T. pallidum* must be performed in light of a positive screening test.

Infectious Lymphadenopathy: Fungal

Fungal lymphadenitis can present in patients who are immunosuppressed and includes histoplasmosis, cryptococcosis, and coccidioidomycosis. Patients often have additional affected organ systems, such as pulmonary and central nervous system. Diagnosis can be made based on fungal antigens, serologic studies, and/or fungal cultures. Enlarged lymph nodes can be seen demonstrating granulomas and yeast on histopathology.[5] Necrotizing granulomas or calcifications can be seen in histoplasmosis. Periodic acid–Schiff (PAS) stains can identify *Histoplasma capsulatum, Cryptococcus neoformans,* and *Coccidioides* organisms.

Infectious Lymphadenopathy: Viral

Epstein-Barr virus (EBV) is the causative agent of infectious mononucleosis. Symptoms can include pharyngitis, fever, and lymphadenopathy.[10] A monospot serologic test can identify heterophile antibodies that agglutinate horse red blood cells and is a sensitive screening test. Polymerase chain reaction (PCR) can be performed if a diagnosis cannot be reached.[11] Caution is advised against lymph node biopsy, especially in young people, given that the characteristic histopathologic features may produce a false-positive diagnosis of lymphoma. On histopathology, there is interfollicular or paracortical expansion of lymphocytes, plasma cells, and dendritic cells. In situ hybridization of EBV RNA or immunostaining for latent membrane protein-1 (LMP-1) can help identify the virus.

Human immunodeficiency virus (HIV) primarily targets CD4 T cells and leads to immunodeficiency. Lymph nodes may or may not be enlarged. Cervical, axillary, and head and neck nodal basins are the most common locations of lymphadenopathy.[12] In acute-stage disease, follicular hyperplasia with numerous lymphoid follicles can be seen in the cortex and medulla. End-stage or late-stage disease is characterized by lymphocyte depletion and lymphoid follicles with few lymphocytes and an increase in dendritic cells and histiocytes.[5,13] Serologic testing for HIV antigens should be done to establish a diagnosis.

Cytomegalovirus lymphadenitis is associated with a mixed reactive pattern on histology, with lymph nodes demonstrating follicular, paracortical, and interfollicular hyperplasia. Herpes simplex virus (HSV) lymphadenitis can show multinucleation of immune and epithelial cells as well as areas of focal necrosis and follicular hyperplasia within the lymph node. Of note, HSV lymphadenitis can occur in tandem with lymphoma.[5,13]

Reactive Hyperplasia

Reactive follicular hyperplasia is most commonly seen in children and may account for 75% of lymphadenopathies seen in children. It is seen in 20% to 30% of adult lymphadenopathies because lymphadenopathies due to malignancy increase with age, but it is nonetheless the most common manifestation of reactive lymphadenopathy.[14,15] An increase in number and size of B-cell–containing lymphoid follicles is evident in reactive follicular hyperplasia. This can happen in response to infection and autoimmune diseases, although in some instances, the specific cause cannot be definitively determined. Follicular hyperplasia can often be associated with hyperplasia of other lymph node compartments.[5] It is critical to distinguish reactive follicular hyperplasia from a neoplastic lymphoid proliferation such as follicular lymphoma (see later discussion), which can be differentiated based on morphologic differences, immunohistochemistry, and possibly flow cytometry. For example, the immunohistochemical marker B-cell lymphoma 2 (BCL-2) is usually not expressed by B cells found in reactive follicular hyperplasia but is often expressed in follicular lymphoma.[5,6]

Reactive paracortical hyperplasia is associated with the paracortical zone of the lymph node, which is enriched in T cells, dendritic cells, and histiocytes. Inflammatory stimuli that cause a T-cell response can lead to paracortical zone expansion, including infection, vaccination, and drugs.[5] The viruses that most commonly cause reactive paracortical hyperplasia are herpes simplex virus, EBV, and cytomegalovirus, although, similar to reactive follicular hyperplasia, sometimes no definitive cause can be identified. The proliferation marker Ki-67 may be increased on immunostaining, and viral immunostains may be helpful as a diagnostic adjunct. T-cell lymphoma should be ruled out with additional molecular studies as necessary.

Autoimmune-Associated Lymphadenopathies

A variety of autoimmune diseases can be associated with lymphadenopathy, including rheumatoid arthritis and systemic lupus erythematosus (SLE). Up to 75% of patients with rheumatoid arthritis can have either generalized or localized lymphadenopathy, with cervical, supraclavicular, and axillary lymph node basins being most commonly affected. Lymph node changes can include reactive follicular hyperplasia with varying follicle sizes and a starry-sky pattern in large germinal centers. Eosinophilic deposits are often present in germinal centers and will demonstrate positive PAS staining. B-lymphocyte immunohistochemistry will demonstrate positivity for CD10 and BCL-6 while being negative for BCL-2.[5,13]

SLE can be commonly associated with lymphadenopathy,[16] either localized or generalized, often involving cervical, mesenteric, axillary, inguinal, and retroperitoneal lymph nodes. During the active untreated phase of the disease, lymph nodes can be necrotic and hemorrhagic, with paracortical hyperplasia and necrosis on histology. Over time, granulation tissue and PAS+ hematoxylin bodies can be seen.[5]

Reactive Lymphadenopathies

Rosai-Dorfman disease is a benign proliferation of histiocytes with massive lymphadenopathy.[17,18] The etiology is unknown. On histopathology, the lymph node demonstrates dilated sinuses filled with a proliferation of histiocytes with abundant eosinophilic cytoplasm and a prominent nucleolus. On immunohistochemistry, it is associated with S100 positivity and negative for CD1a.[5,13]

Kimura lymphadenopathy is a chronic inflammatory disorder affecting subcutaneous tissue and regional lymph nodes of the head and neck, mainly seen in young Asian males.[19] Lymph nodes demonstrate reactive follicular hyperplasia and extensive eosinophilia with microabscesses. IgE deposits can be seen in germinal centers. Cytopathology is of limited importance in the diagnosis of Kimura disease.[5,13]

Castleman disease usually presents as a localized and benign lymphoproliferative lesion in young adults. Histopathology demonstrates large follicles with involuted germinal centers, with follicular dendritic cells positive for CD21, CD23, CD35, and epidermal growth factor receptor (EGFR).[5,13] Excision alone is often curative.

Sarcoidosis is a systemic granulomatous disease that is often a diagnosis of exclusion. Most patients with sarcoidosis present with intrathoracic lymphadenopathy and pulmonary disease,[20] with imaging showing bilateral hilar lymphadenopathy and possibly lung nodules. Sarcoidosis can involve any organ and is histologically characterized by nonnecrotizing granulomatous inflammation. Lymph nodes are often involved with granulomas without signs of acute inflammation or necrosis. Erythrocyte sedimentation rate and serum angiotensin-converting enzyme levels are often elevated. It is important to rule out lymphoma and leukemia because these malignant diseases can coexist in the same lymph node biopsy specimen as sarcoidosis.[5,13]

Lymphoma/Leukemia

Hodgkin lymphoma (HL) is organized into two major categories, nodular lymphocyte predominant and classic.[21] Classic type makes up approximately 90% to 95% of all HL and includes nodular sclerosis, lymphocyte-rich, mixed cellularity, and lymphocyte-depleted subtypes. These neoplasms arise from germinal center B-cell precursor cells and transform into the malignant Reed-Sternberg and Hodgkin cells. Over 90% of the cells within the neoplasm are reactive immune cells, including lymphocytes, histiocytes, plasma cells, and neutrophils. Nodular lymphocyte-predominant HL stains positively for CD20 on immunohistochemistry and negatively for CD30 and CD15, which stain classic HL.[22] Staging is based on degree and location of lymph node or organ involvement.

In general, fine-needle aspiration (FNA) is a safe and accurate tissue-sampling technique in the evaluation of lymphadenopathy, particularly in the evaluation of suspected nonlymphoproliferative malignancies. Lymph node FNA has approximately 90% accuracy with rare false-positive results.[23,24] False-negative diagnoses are more commonly seen, possibly due to partial lymph node involvement or insufficient sampling. It is important to note, however, that FNA is less sensitive for the diagnosis of lymphomas compared with metastatic carcinoma or melanoma. Core-needle biopsy has demonstrated reasonable accuracy for lymphoma in the setting of cervical lymphadenopathy.[25] Although FNA or core-needle biopsy may be very reasonable first starting points for otherwise unspecified lymphadenopathy, if there is high suspicion for lymphoproliferative disorder (or if the results of needle biopsy are nondiagnostic), consideration for excisional lymph node biopsy would be indicated. For HL specifically, identification of Reed-Sternberg cells can be greatly facilitated with excisional biopsy. In circumstances where a lymph node is not readily accessible for excisional biopsy, a combination of core-needle biopsies and FNA in conjunction with appropriate ancillary testing may be sufficient for a diagnosis.

Lymphoblastic leukemia/lymphoma comprises B-lymphoblastic leukemia/lymphoma (B-ALL/LBL) and T-lymphoblastic leukemia/lymphoma (T-ALL/LBL).[26] B-cell lymphomas are more common than T-cell lymphomas and are most commonly seen in children. They display a high degree of molecular heterogeneity, with multiple classifications, including *ETV6-RUNX1* positive, *BCR-ABL1* positive, and hyperdiploidy.[22] Lymph node histopathologic findings in B-LBL and T-LBL are very similar and difficult to distinguish from one another. In general, the lymph node architecture becomes completely replaced with the neoplasm, which appears as monomorphous lymphoblasts infiltrating the lymph node capsule and extending into perinodal soft tissue. Immunostains can help distinguish between T- and B-cell neoplasms. Almost all B-ALL/LBL neoplasms will express CD19, CD79a, and TdT, and most will express CD10, CD22, and CD20. T-ALL/LBL neoplasms often express CD7, CD52, and CD3.[22]

Mature B-cell lymphomas involving lymph nodes include a wide range of neoplasms, such as chronic lymphocytic leukemia, mantle cell lymphoma, diffuse large B-cell lymphoma, and follicular lymphoma.[27] Lymph nodes are often diffusely replaced by lymphoma. Immunophenotyping and molecular analyses are important in identifying the underlying diagnosis. Chronic lymphocytic leukemia is often positive for CD5 and negative for CD10. Mantle cell lymphomas are positive for CD23, cyclin D1, and SOX11. Diffuse large B-cell lymphomas are generally positive for B-cell markers such as CD19, CD20, CD22, and CD79a.[22]

Follicular lymphoma is one of the most common lymphomas in Western society.[28] It is a malignancy that involves germinal center B cells. The lymph node architecture is often completely effaced by neoplastic follicles that extend through the capsule and into perinodal soft tissue. Follicular lymphomas are usually positive for CD19, CD20, CD22, CD79a, and BCL-6 and negative for CD5. The molecular hallmark of follicular lymphoma is the t(14;18)(q32;q21) rearrangement, which results in overexpression of BCL-2. Fluorescence in situ hybridization or PCR can be used to identify this rearrangement. About 30% of patients with follicular lymphoma will transform to diffuse large B-cell lymphoma, which is high grade and associated with resistance to therapy and short median overall survival.[5,13,29] Positron emission tomography (PET)/CT is preferred over CT for staging because PET/CT has been found to alter therapy and is associated with a decreased rate of histologic transformation.[30] In addition, PET/CT can help identify lymph nodes with the highest fluorodeoxyglucose (FDG) uptake, which can then be targeted for excisional biopsy.

Mature T-cell lymphomas involving lymph nodes include peripheral T-cell lymphoma, adult T-cell lymphoma, and anaplastic large-cell lymphoma. T-cell lymphomas are less common than B-cell lymphomas. They generally are seen to replace the lymph node architecture and can be distinguished from B-cell lymphomas by showing positivity for T-cell markers such as CD2 and CD3.[22]

IMAGING FOR LYMPHADENOPATHY

In most cases of unexplained lymphadenopathy, imaging is an important adjunct during the diagnostic evaluation. Imaging allows for more accurate characterization of the abnormal lymph nodes and overall distribution of the lymphadenopathy as well as assisting in guiding the biopsy approach, which is of particular importance in oncology to ensure a definitive diagnosis can be rendered. Common imaging techniques include ultrasound (US), computed tomography (CT), PET/CT, or magnetic resonance imaging (MRI).

Ultrasound

US, which may be a combination of gray scale and/or Doppler sonography, is well established and commonly used for evaluating lymphadenopathy. Multiple nodal characteristics can be assessed, such as nodal site, size, shape, internal architecture, and vascular pattern (Fig. 71.2). Although no single sonographic criterion can accurately differentiate a reactive from a malignant lymph node, when combined with the clinical history, it can frequently help to further differentiate the two processes, with reported sensitivity and specificity of 97% and 93%, respectively.[31]

Size: The size of normal lymph nodes varies and depends on their location. Cervical lymph nodes tend to be the smallest, whereas axillary and inguinal lymph nodes can be much larger. Given the inconsistency in nodal size throughout the body, size alone is insufficient for differentiating a reactive versus malignant process.[32] However, assessment of nodal size can be beneficial during surveillance imaging; fluctuations in size may be more suggestive of a reactive process, whereas interval enlargement would increase the suspicion for an underlying cancer and the need for biopsy.[33]

Shape: Normal lymph nodes have a classic oval or reniform shape. Reactive processes, which can lead to nodal enlargement, tend to preserve the classic lymph node architecture. In contrast, when lymph nodes develop a rounded shape, this finding is more concerning for a malignant process. The "shape index," which is defined as the ratio between the short and long axis of the node, has been proposed as a criterion to differentiate benign and malignant nodes.[34] Normal lymph nodes commonly have a long-axis diameter two times the short-axis diameter. As a result, lymph nodes that have a shape index greater than 0.5 correspond to a rounded shape, which is more concerning for a malignant node.

Hilum: Normal lymph nodes possess an echogenic hilum as a result of the blood vessels and fatty tissue that reside within this space. When tumor infiltrates the normal nodal tissue, this can result in the loss of an echogenic hilum, or "fatty hilum."[35] Up to 92% of benign lymph nodes will have a preserved echogenic hilum as compared with only 4% of malignant nodes.

Additional sonographic characteristics: Normal, reactive, and malignant lymph nodes tend to have a hypoechoic cortex. However, if necrosis or calcifications are noted on US, despite the presence of a hypoechoic cortex, these specific sonographic features are often suggestive of a malignant node.[36] Lastly, Doppler US can be a useful adjunct in assessing vascular distribution.[37] Hilar flow, which describes blood flow branching radially from the hilum, is commonly seen in normal nodes. Conversely, peripheral flow is more frequently observed in malignant

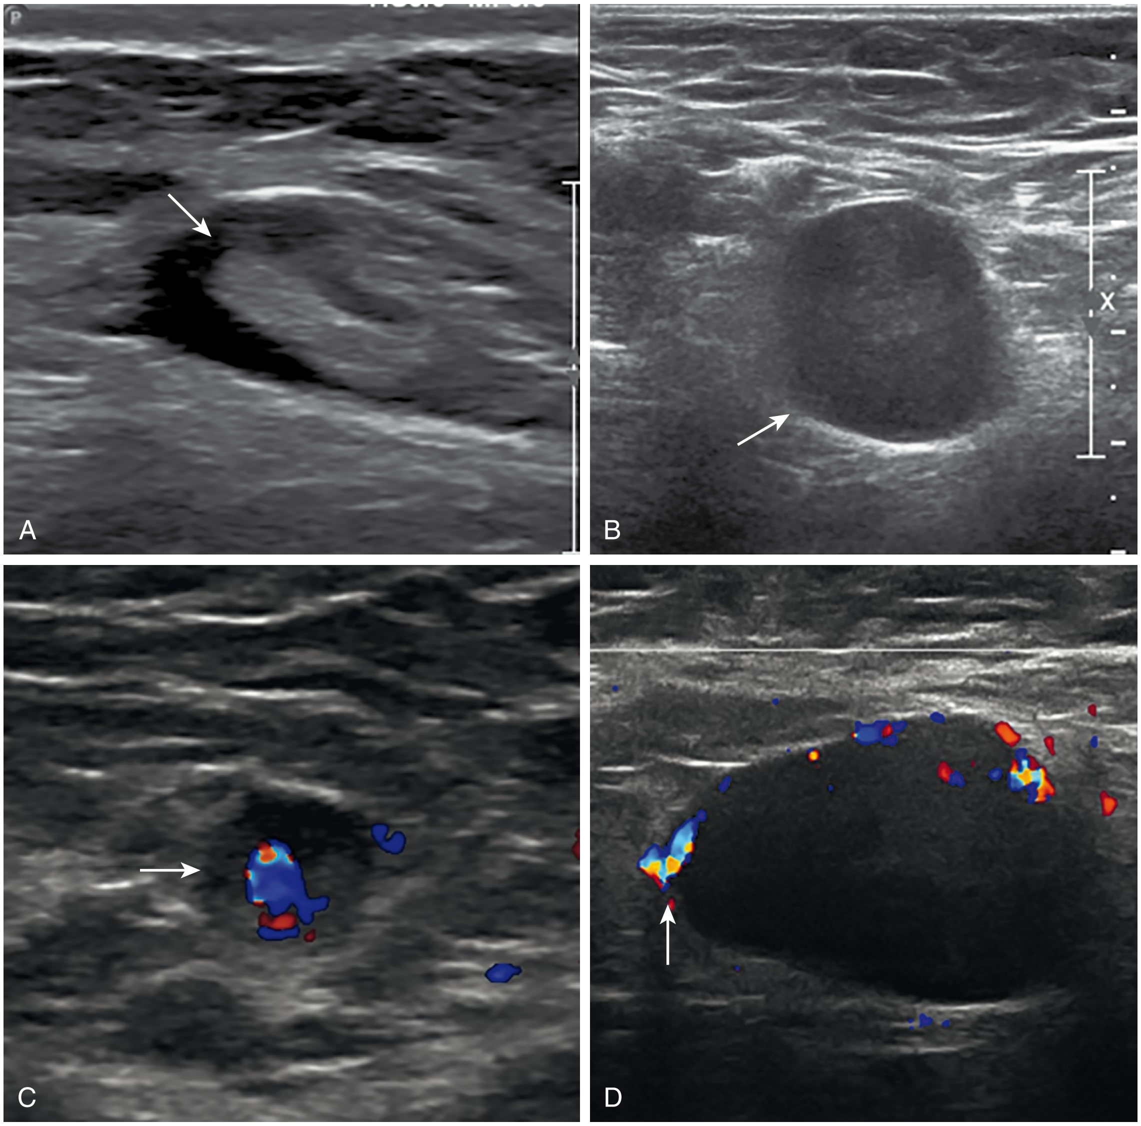

FIGURE 71.2 Ultrasound characteristics of benign versus malignant lymph nodes. (A) Normal oval-shaped axillary lymph node with preserved fatty hilum *(arrow)*. (B) Malignant lymph node with rounded shape *(arrow)* and loss of fatty hilum. (C) Normal lymph node with hilar blood flow. (D) Abnormal lymph node with peripheral blood flow *(arrow)*.

nodes. As tumor infiltrates the nodal cortex, this can lead to the displacement of hilar vessels to the periphery of the node, resulting in blood flow occurring around the edges.

Computed Tomography/Positron Emission Tomography–Computed Tomography/Magnetic Resonance Imaging

CT, PET/CT, and MRI are effective imaging modalities for evaluating lymph node size, character (necrotic/cystic), and distribution. If there is concern for generalized lymphadenopathy, these imaging techniques can quickly determine the extent of the lymphadenopathy and the lymph node basins involved and evaluate the relationship of the lymphadenopathy to surrounding anatomic structures. Additionally, cross-sectional imaging allows for assessment of mediastinal, mesenteric, and retroperitoneal lymphadenopathy, lymph node basins not easily evaluated by ultrasound or physical examination.[38] Radiographic size thresholds for determining abnormal lymphadenopathy have been proposed, but depending on the location and size cutoff, this will ultimately affect the sensitivity and specificity of the study. Unlike CT and MRI, where the primary metric captured is size, PET/CT has the additional advantage of assessing lymph node function/metabolism, whereby standardized uptake values (SUVs) are measured, leading to an increase in study accuracy. Of the three imaging techniques, PET/CT maintains the highest sensitivity (94%) and specificity (96%) in identifying malignant lymph nodes.[38] With CT or MRI, the reported sensitivity and specificity in the evaluation of abnormal lymphadenopathy are 90% and 94% and 86% and 94%, respectively.[39]

LYMPH NODE BIOPSY

If there is any concern for malignancy, or the lymphadenopathy is unexplained or persistent despite appropriate targeted laboratory studies, lymph node biopsy should be considered. Determining which lymph node to biopsy is extremely important because it increases the likelihood of making a diagnosis and avoids additional unnecessary procedures.

Traditionally, the most abnormal node or, in the setting of isolated lymphadenopathy, a single node is targeted for biopsy. If the adenopathy is diffuse and no single node predominates, clinicians have several options that could help guide the biopsy approach and technique. When involving the superficial lymph node basins, all other diagnostics being comparable, one can consider the order of anatomic biopsy preference to be guided by efforts to reduce surgical morbidity. Occasionally, the lymphadenopathy may be confined to deeper compartments. For mediastinal lymphadenopathy, depending on the location, sampling may require a bronchoscopy or mediastinoscopy. Early engagement of thoracic surgery and/or interventional pulmonology may be beneficial in these scenarios. There are several approaches to addressing isolated mesenteric/retroperitoneal lymphadenopathy. Depending on the location, biopsy approaches can be by image guidance, endoscopic, or surgical (laparoscopic/robotic/open). Lastly, if lymphoma is suspected, PET/CT can be extremely helpful for identifying the lymph node with the greatest SUV.[40] This will ensure that the highest-grade lymphoma is being captured, which is important for treatment planning (Fig. 71.3). This may be particularly relevant in the setting of follicular lymphoma when there may be concern for transformation to large B-cell lymphoma.

There are several biopsy options available, but the approach will depend on the location of the lymphadenopathy and suspected diagnosis.

Fine-needle aspiration (FNA): FNA is a widely used biopsy technique that is effective, is low risk, and consumes low resources.[41] The biopsy can be done in clinic and may occasionally require image guidance. When the cytologic analysis is combined with immunohistochemistry studies, its accuracy is high, with a low false-positive rate (0.9%).[42] Solid organ malignancies (head and neck, lung, breast, gastrointestinal) and cutaneous malignancies (melanoma, cutaneous squamous cell carcinoma) can frequently be diagnosed by FNA. Given the lack of tissue obtained, limitations of FNA include inability to run ancillary diagnostic tests (next-generation sequencing) and a high false-negative rate (3.4%).[42] Additionally, assessment of nodal architecture is not possible. As a result, if lymphoma is suspected, FNA will often be ineffective at rendering a definitive diagnosis.[43]

Core-needle biopsy: If more tissue is required to establish a diagnosis or special studies such as immunophenotypic, genetic, or molecular analyses are anticipated, then core-needle biopsy is an effective approach. Additionally, nodal architecture can occasionally be captured, allowing for appropriate lymphoma evaluation.[44] For lymph nodes that are not easily accessible and for which a surgical approach would yield significant morbidity, core-needle biopsy should be considered over an open surgical biopsy.

Excisional/open biopsy: In cases where needle biopsy is inconclusive or lymphoma is suspected, excisional biopsy can be considered.[40,45] Although the most invasive of the three biopsy techniques, it allows for complete histologic and architectural lymph node assessment. Most excisional lymph node biopsies are performed under general anesthesia, but for superficially located nodes, the procedure can be selectively performed with monitored anesthesia care (MAC) or local anesthesia. Morbidity, albeit low, is most common after excisional biopsy compared with the other approaches. Complications include bleeding, infection, seroma/lymphocele development, nerve injury, and lymphedema, with most cases being self-limiting and mild in severity.

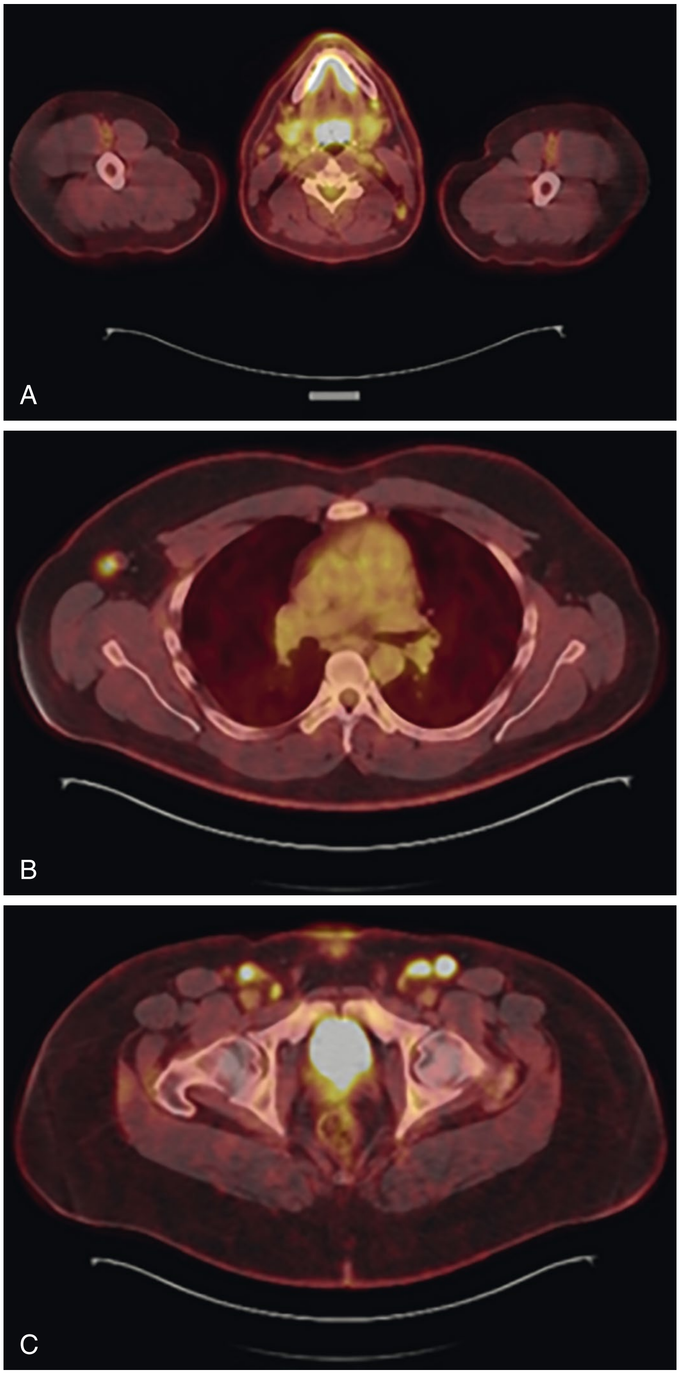

FIGURE 71.3 Seventy-year-old male with a history of new lymphadenopathy. Positron emission tomography scan revealed hypermetabolic lymph nodes in the (A) cervical, (B) axillary, and (C) inguinal lymph node basins. The inguinal lymph nodes had the highest standardized uptake value (14). Excisional biopsy of the inguinal lymph node revealed a grade 3A follicular lymphoma.

METASTASES FROM TUMOR OF UNKNOWN PRIMARY

Lymphadenopathy can sometimes be due to metastases from a nonhematologic malignancy to the regional nodal basin. The histologic pattern of lymph node metastases is often similar to that of the primary tumor, except in cases of very poorly differentiated tumors. Determination can be made between adenocarcinoma, squamous cell carcinoma, melanoma, and neuroendocrine tumors. There are also associated histologic features, such as mucus secretion, signet ring cells, papillary architecture, keratin pearls, clear cell features, and melanin pigmentation, which may help give clues as to the tumor of origin. Immunohistochemistry can be particularly helpful. Cytokeratin staining can help identify a malignancy of epithelial origin. Synaptophysin can be used to identify neuroendocrine tumors, and S100 can help identify tumors of melanocyte origin. Breast metastases to lymph nodes often express estrogen and progesterone receptors, whereas thyroid transcription factor-1 (TTF-1) can help identify the thyroid as a source of cervical lymphadenopathy and the lung as a source of mediastinal lymphadenopathy.

Workup and Management of Metastatic Tumors of Unknown Primary

The site of lymphadenopathy may provide important clues to the origin and site of the primary tumor (Table 71.3).

In cases of axillary lymphadenopathy with pathologic findings from FNA suggestive of a breast primary, a core-needle biopsy of the lymph node is typically required to allow staining for estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2). Every effort should be made to identify the presence and location of the breast primary using a combination of mammogram, ultrasound, and MRI. Treatment will likely involve neoadjuvant chemotherapy followed by definitive surgery and radiation in those without metastatic disease.[46] Postmenopausal patients with ER-positive and HER2-negative disease who have a low nodal burden can sometimes proceed straight to surgery followed by adjuvant chemotherapy, as determined by number of lymph nodes involved on final pathology or Oncotype DX of the primary tumor.[47] In fewer than 1% of cases, the tumor is occult, and a breast primary cannot be identified on imaging. In these cases, the breast can be treated with either mastectomy or radiation. Patients going to up-front surgery will require axillary dissection with removal of levels I and II axillary lymph nodes. Patients undergoing neoadjuvant chemotherapy can have the most suspicious lymph node clipped, followed by a sentinel lymph node biopsy with retrieval of the clipped node in cases where lymphadenopathy clinically resolves with chemotherapy.[48] Should the sentinel lymph node biopsy be positive for residual nodal disease, a completion axillary dissection would be warranted. Strong consideration should be given to avoidance of excisional biopsy to obtain a diagnosis in cases of suspected breast cancer because the success of a second sentinel lymph node biopsy performed after an initial sentinel lymph node biopsy before neoadjuvant chemotherapy may be significantly lower.[49]

TABLE 71.3 Regional Lymph Node Metastases and Common Origins of Primary Tumors

LOCATION OF LYMPHADENOPATHY	ORIGIN OF PRIMARY TUMOR[a]
High cervical	Nasopharynx, tonsils, tongue, thyroid, larynx, face and scalp
Low cervical	Pulmonary, intraabdominal
Virchow's lymph node (left supraclavicular)	Intraabdominal and pelvic (gastric)
Axillary	Breast, upper extremities, trunk
Inguinal	Lower extremities, cervix, vulva, endometrium, ovary, rectum, anus, penis, prostate
Pelvic	Prostate, testes, gynecologic organs, lower extremities

[a] Melanoma can present at any of these nodal basin sites.

Adapted from Miranda RN, Khoury JD, Medeiros LJ. *Atlas of Lymph Node Pathology*. New York: Springer; 2013; Medeiros LJ. *Loachim's Lymph Node Pathology*. Philadelphia: Wolters Kluwer Health; 2022.

In cases of suspected primary melanoma, a thorough history and physical examination will be critical in identifying any potential lesions. Ideally, a core-needle biopsy or FNA would be performed for diagnosis rather than excisional biopsy, particularly for a single enlarged pathologic node, to allow for the possibility of neoadjuvant therapy. Complete staging imaging (ideally with PET/CT and brain imaging) and *BRAF* mutation testing should be obtained. In cases of resectable nodal disease, either up-front surgery with wide local excision of the primary tumor (if identified) and a therapeutic lymph node dissection or neoadjuvant therapy can be pursued. Major pathologic response (<10% viable tumor) to neoadjuvant immune checkpoint blockade (with the programmed cell death 1 [PD-1] inhibitor pembrolizumab) has been shown to correlate with durable disease-free survival after surgery, and there are data to support that such an approach combined with adjuvant therapy may yield more favorable outcomes with respect to event-free survival compared with adjuvant therapy alone.[50] Moreover, a neoadjuvant approach may obviate the need for more extensive lymphadenectomies with associated morbidity if an index node removal demonstrates a major pathologic response. A therapeutic lymph node dissection, which remains the standard approach for disease localized to a nodal basin, requires an anatomically complete dissection of the involved nodal basin. In the axilla, a level I–III dissection should be performed. In the groin, an inguinofemoral dissection is sufficient for clinically evident nodal disease, although therapeutic iliac and obturator lymph node dissection may be considered if imaging shows resectable lymphadenopathy at these locations. Systemic adjuvant therapy options consist of immunotherapy with nivolumab or pembrolizumab, or a BRAF/MEK inhibitor for patients with *BRAF V600* activation mutations. In high-risk patients, adjuvant radiation may be selectively considered to the nodal basin based on location, number of involved lymph nodes, and presence of extracapsular extension.

For cervical lymphadenopathy concerning for a head and neck primary, a history and complete head and neck examination, including examination of the skin, nasopharynx, oropharynx, hypopharynx, and larynx and palpation of the oropharynx, should be performed with mirror and fiberoptic examination. Image-guided FNA of the lymph node should be performed to help differentiate between a likely head and neck malignancy and other pathologies, such as thyroid cancer, lymphoma, or melanoma. Workup entails a CT or MRI with contrast of the skull base through the thoracic inlet. If targeted imaging fails to identify a primary, PET/CT should be performed before additional interventions, such as examination under anesthesia and more invasive workup studies. Human papillomavirus (HPV) and EBV testing can be performed for squamous cell or undifferentiated histology. For cervical node levels I, II, III, and upper V, an examination under anesthesia, biopsy of areas of concern, tonsillectomy, and direct laryngoscopy and nasopharyngeal assessment should be performed. For cervical node levels IV and lower V, an examination under anesthesia, direct laryngoscopy, esophagoscopy, and bronchoscopy should be performed. Subsequent treatment will be based on standard regimens for the primary tumor. For thyroglobulin-negative and calcitonin-negative adenocarcinoma occult primaries, a neck dissection, and if high in the neck, parotidectomy, should be performed. For squamous cell occult primaries, appropriate neck dissection or possibly radiation should be performed.

Bullet Points

1. Differential for lymphadenopathy is broad and includes benign and malignant etiologies.
2. If suspicion is high for malignancy or for benign etiology, either symptomatic or for which diagnostic tissue could influence medical management, a lymph node biopsy may be warranted.
3. Methods of lymph node biopsy include FNA, core-needle biopsy, and surgical excisional lymph node biopsy. The decision for biopsy type should take into account potential morbidity of biopsy methods and amount of tissue needed for accurate histologic diagnosis. FNA is usually effective at diagnosis for tumors metastatic to lymph node, whereas core-needle biopsy may provide additional tissue if molecular diagnostics are needed to guide therapy. Surgical biopsy is often indicated in cases where lymphoproliferative disorder is suspected to obtain lymph node architecture and adequate tissue for flow cytometry and other ancillary studies.
4. Ultrasound is a particularly sensitive, specific, and cost-effective diagnostic imaging modality for assessing potentially pathologic lymphadenopathy and for nodal ultrasound surveillance; PET/CT (using SUV avidity) may be particularly helpful in helping to target a specific node or nodal basin in cases of lymphoma where there may be a mixed pattern of disease (with higher- and lower-grade components)
5. In cases of isolated node lymphadenopathy with the potential for nodal metastasis from an unknown primary, special attention should be given to avoiding excisional biopsy of the isolated node and considering the possibility of a potential role for neoadjuvant therapy.
6. Management of localized lymphadenopathy of unknown primary will vary by tumor histology; regional therapeutic lymphadenectomy with appropriate anatomic level of dissection and neoadjuvant therapy may be appropriate considerations.

  Other Considerations

SPLENIC ANATOMY

The spleen is the largest lymphatic organ in the body; it measures 7 to 13 cm in length and weighs up to 250 g. It develops as a discernible organ from mesenchymal cells in the dorsal mesogastrium during week 5 of embryogenesis. The spleen is initially adherent to dorsal pancreatic bud and ultimately separates from the pancreatic bud and settles into the left uppermost aspect of the abdomen in the intraperitoneal cavity. Anatomically, it is located in the upper abdomen protected by ribs 9, 10, and 11. In healthy adults, it is not palpated below the costal margin. In infants, however, it is palpable below the costal margin at the midaxillary line. The spleen has both a diaphragmatic surface and visceral surface, which abuts the greater curvature of the stomach, splenic flexure of the colon, apex of the left kidney, and tail of the pancreas (Fig. 72.1). Peritoneal reflections along these surfaces suspend the spleen in the peritoneal cavity (Fig. 72.2). The splenophrenic ligament is along the diaphragmatic surface, whereas the gastrosplenic, splenorenal, and splenocolic ligaments are related to the visceral surface. In patients without portal hypertension, the splenophrenic and splenocolic ligaments are relatively avascular. The gastrosplenic ligament carries the short gastric vessels in its superior aspect and the left gastroepiploic in its inferior aspect. The splenorenal ligament houses the splenic artery and vein as well as the tail of the pancreas. The tail of the pancreas abuts the splenic hilum in 30% of individuals and is within 1 cm of the hilum in 70% of cases.

Vascular Anatomy

The splenic artery, a branch of the celiac trunk, together with its branches of the short gastric arteries provide the arterial blood supply to the spleen. The splenic artery is a tortuous vessel that gives off multiple branches (up to 16–18) to the pancreas as it travels along its posterior aspect (Fig. 72.3). There are two common variations of the splenic artery with regard to the relation between the splenic artery branches and the hilum of the spleen: the magistral type, which branches into terminal and polar arteries near the hilum of the spleen, and the distributed type, which arborizes much more proximally and distantly from the hilum. A distributed anatomy of the artery is found in 70% of the population.

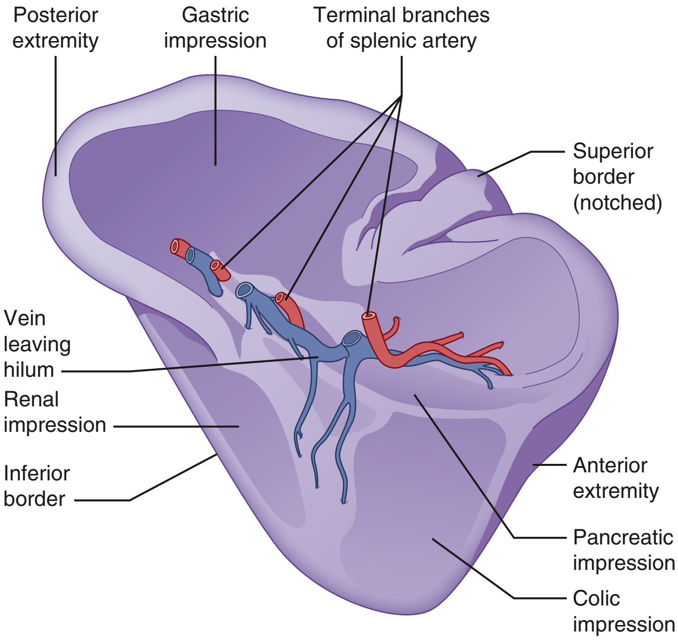
The splenic artery commonly branches into four to six polar arteries, which go to lobes of the spleen dividing into terminal arteries within the organ, and six short gastric arteries, which often are connected, or come off of, the superior polar artery.

The large splenic vein, which travels posteriorly to the pancreas, is created by the union of several splenic veins and the left gastroepiploic vein, joining with pancreatic branches, and often the inferior mesenteric vein, to form the portal vein with the superior mesenteric vein.

The spleen is encased within a fibroelastic capsule. From the capsule, trabeculae extend and compartmentalize the spleen into lobules. The spleen is also segmented by the divisions of the splenic vessels as they branch within the organ and merge with these trabeculae (Figs. 72.4 and 72.5). The arterioles branch into even smaller vessels and leave these trabeculae to merge with the splenic pulp, where their adventitia is replaced by a covering of lymphatic tissue that continues until the vessels thin to capillaries. There are two general types of tissue within the spleen known as white and red pulp. The majority of the spleen is red pulp, and the vasculature, connective tissue, and venous sinuses are the key aspects of this portion. The lymphatic sheaths make up the white pulp of the spleen and are interspersed among the arteriolar branches as lymphatic follicles. The white pulp interfaces with the red pulp at the marginal zone of the spleen. It is in this marginal zone that the arterioles lose their lymphatic tissue, and the vessels evolve into thin-walled splenic sinuses and sinusoids. The sinusoids then merge into venules, draining into veins that travel along the trabeculae to form larger splenic veins that mirror their arterial counterparts.

SPLENIC FUNCTION

The spleen has four main functions in humans.



Posterior extremity
Gastric impression
Terminal branches of splenic artery
Superior border (notched)
Vein leaving hilum
Renal impression
Inferior border
Anterior extremity
Pancreatic impression
Colic impression

The more common distributed type of anatomy (B) occurs in 70% of individuals. (From Economou SG, Economou TS. *Atlas of Surgical Techniques*. Philadelphia: WB Saunders; 1966:562.)

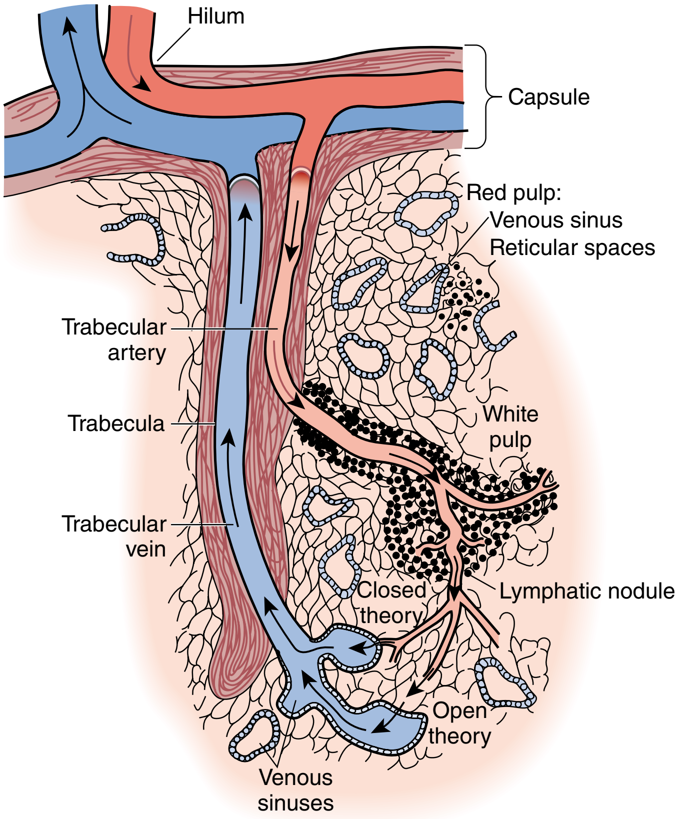

FIGURE 72.4 Structure of the sinusoidal spleen showing the open and closed blood flow routes. (From Bellanti JA. *Immunology: Basic Processes*. Philadelphia: WB Saunders; 1979.)

Hematopoietic

Between 3 and 5 weeks of fetal life, the spleen is a key producer of white and red blood cells and continues along with the liver as gestation progresses. The bone marrow begins to ramp up production during the fifth month of gestation, and under normal conditions, the spleen has no significant hematopoietic function beyond this point. However, in certain pathologic conditions such as myelodysplastic syndrome, the spleen is one of the main organs involved in extramedullary erythropoiesis.

Reservoir

The spleen functions as a reservoir specifically for platelets. Normally one-third of the platelets are pooled within the spleen. Thus, patients with splenomegaly are able to sequestrate a large volume of platelets (up to 80%) with resultant thrombocytopenia.

Filtration

The splenic filtration process consists of two methods of blood flow: the closed and open systems. In the closed system, blood flows directly from arteries to veins. In the open system, the blood flows through the arterioles and then trickles through a sievelike parenchyma made up of reticuloendothelial cells into the splenic sinuses before draining into the venous system (see Figs. 72.4 and 72.5). The cellular elements of blood are directed toward these reticuloendothelial cells, in which cellular cleansing processes take place. These include removal of senescent cells, cellular inclusions (e.g., RBC nucleoli) and parasites, and the sequestration of red blood cells (RBCs) (for maturation) and platelets (reservoir). The plasma is directed to the lymphoid tissue, where soluble antigens stimulate the production of antibodies.

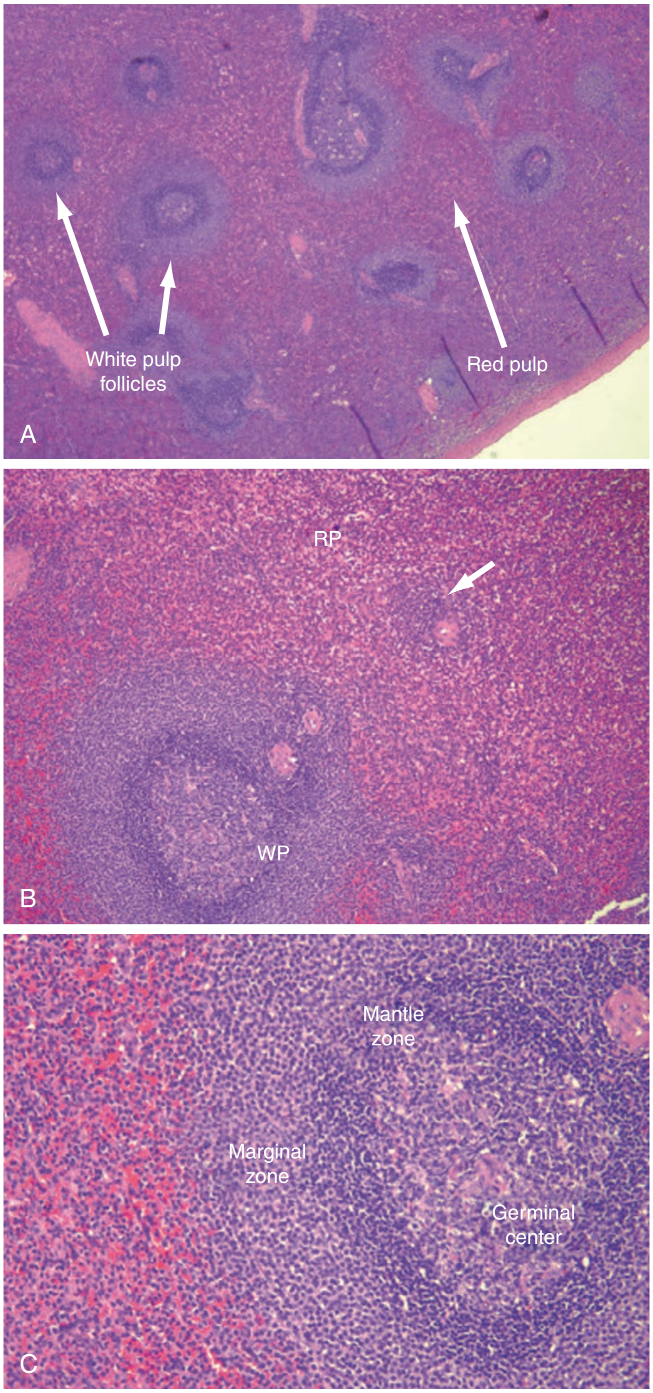

FIGURE 72.5 Normal human spleen on hematoxylin-eosin staining. (A) Low-power photomicrograph showing relationship and relative proportions of red and white pulp. (B) Medium-power photomicrograph (*arrow* indicates periarterial lymphoid sheath). (C) High-power photomicrograph showing detailed secondary follicle architecture. *RP,* Red pulp; *WP,* white pulp (secondary follicle). (From Pernar LIM, Tavakkoli A. Anatomy and physiology of the spleen. In: Yeo CJ, ed. *Shackelford's Surgery of the Alimentary Tract*. 8th ed. Philadelphia: Elsevier; 2019:1595.)

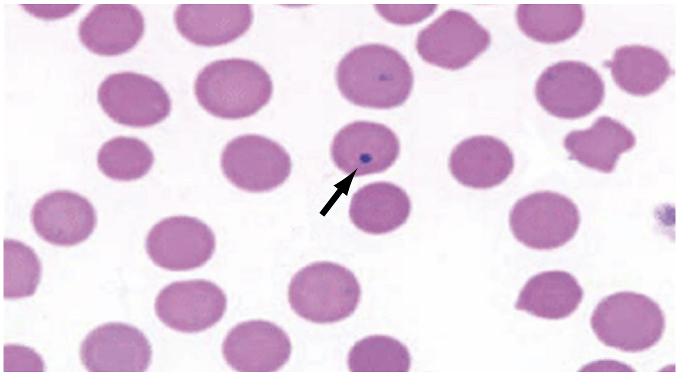

FIGURE 72.6 The presence of Howell-Jolly bodies *(arrow)* on the peripheral blood smear is suggestive of asplenia or hyposplenism. (From Hashimoto N. Management of overwhelming postsplenectomy infection syndrome. *Clin Surg.* 2016;1:1148.)

RBC morphology, and thus RBC function, is maintained by splenic filtration. Normal RBCs are biconcave and deform easily. This plasticity allows passage through the microvasculature and optimizes the exchange of oxygen and carbon dioxide. Imperfect RBCs with inclusions such as Howell-Jolly bodies (nuclear remnant), Heinz bodies (denatured hemoglobin), Pappenheimer bodies (iron granules), and abnormally structured cells such as acanthocytes (spur cells) and codocytes (target cells) cause these RBCs to undergo removal in the spleen.

The presence of Howell-Jolly bodies on a peripheral blood smear is one of the most characteristic findings in asplenia, whether surgical or medical (hemoglobinopathies) (Fig. 72.6). Howell-Jolly bodies are strongly basophilic inclusion bodies found in the cytoplasm of RBCs and represent nuclei remnants that were unable to be cleared by the spleen. Aged RBCs with decreased plasticity (>120 days) become trapped and destroyed in the spleen. Abnormal erythrocytes that result from hemoglobinopathies such as sickle cell anemia, hereditary spherocytosis (HS), thalassemia, or pyruvate kinase deficiency (PKD) are also trapped and destroyed by the spleen. The overall effect is worsening anemia, splenomegaly, and sometimes autoinfarction of the spleen. Similarly, the spleen is involved in platelet destruction in immune thrombocytopenia (ITP), formerly known as *idiopathic thrombocytopenia purpura.*

Immunity

The spleen assists in managing the immune response by antibody synthesis and phagocytosis. Asplenic patients have been found to express subnormal immunoglobulin M levels, and their peripheral blood mononuclear cells exhibit a suppressed immunoglobulin response. Other factors involved in the immune response are opsonins, such as properdin and tuftsin. Opsonins, produced in the spleen, exhibit reduced serum levels after splenectomy. Properdin, a globulin protein also known as *factor P,* initiates the alternate pathway of complement activation; this increases the destruction of bacteria and abnormal cells. Tuftsin, a tetrapeptide, enhances the phagocytic activity of mononuclear phagocytes and polymorphonuclear leukocytes. Absence of a circulating mediator appears to result in suppressed neutrophil function. The spleen also plays a key role in cleaving tuftsin from the heavy chain of immunoglobulin G; thus, circulating levels of tuftsin are subnormal in asplenic patients. Additionally, splenic filtration may be particularly important for removal of microorganisms for which the host does not have a specific antibody (Box 72.1). The immune functions of the spleen become evident after splenectomy, when patients are noted to be at risk for infections related to encapsulated bacteria *Streptococcus pneumoniae, Haemophilus influenza,* and *Neisseria meningitidis.*

BOX 72.1 Biologic Substances Removed By the Spleen

Normal Subjects

Red blood cell membrane
Red blood cell surface pits and craters
Howell-Jolly bodies
Heinz bodies
Pappenheimer bodies
Acanthocytes
Senescent red blood cells
Particulate antigen

Patients With Disease

Spherocytes (hereditary spherocytosis)
Sickle cells, hemoglobin C cells
Antibody-coated red blood cells
Antibody-coated platelets
Antibody-coated white blood cells

SPLENECTOMY

Splenectomy may be indicated for conditions other than trauma. These indications encompass mainly hematologic disorders in addition to other mass lesions and splenic vascular lesions that are discussed elsewhere in this textbook.

Benign Hematologic Conditions

Immune Thrombocytopenia

ITP is the most common hematologic indication for splenectomy. Previously known as *idiopathic thrombocytopenic purpura,* the naming was adjusted to *immune thrombocytopenia* in 2009 to reflect a better understanding of the disease process and the absence of purpura in most cases.[1] ITP is characterized by a low platelet count below 100 × 10^9/L despite normal bone marrow and the absence of other causes of thrombocytopenia that could be responsible for the finding.[2] The pathogenesis is not fully understood; however, immunoglobulin G autoantibodies directed toward the platelet membranes are believed to be responsible for platelet destruction within the reticuloendothelial system by macrophages and cytotoxic T cells. In addition to the destruction, there is dysfunction of megakaryocytes with a low level of thrombopoietin.

ITP has a heterogenous clinical presentation and course and can be classified as either primary—without any underlying cause—or secondary—related to an autoimmune or infectious cause. Primary ITP is further classified into three subtypes based on disease chronicity: newly diagnosed (within 3 months), persistent (3–12 months), and chronic (greater than 12 months). Secondary ITP is the result of a known cause such as medication induced, infectious, or rheumatologic conditions (i.e., systemic lupus erythematosus). Presentation of ITP can vary, and bleeding episodes may be minor (including bruising and petechiae) or severe, including life-threatening gastrointestinal or intracerebral hemorrhage.[3] In general, patients with ITP have significantly impaired health-related quality of life and have a 1.3- to 2.2-fold higher mortality rate than the general population.[4,5]

The diagnosis of primary ITP involves the exclusion of other causes of thrombocytopenia—pregnancy, drug induced thrombocytopenia (e.g., heparin, quinidine, quinine, sulfonamides), viral infections, and hypersplenism (Box 72.2). Mild thrombocytopenia may be seen in approximately 6% to 8% of otherwise normal pregnancies and in up to 25% of females with preeclampsia. Drug-induced thrombocytopenia is thought to occur rarely, in approximately 20 to 40 cases/million users of common medications, such as trimethoprim-sulfonamide and quinine. Other medications, such as gold salts, have a higher incidence—almost 1% of users. Viral infection (e.g., hepatitis C, human immunodeficiency virus [HIV] infection, rarely Epstein-Barr virus infection) can be responsible for thrombocytopenia independent of splenic sequestration. Bacterial infection, specifically *Helicobacter pylori,* has also been linked to infection-related thrombocytopenia that improves with eradication.

BOX 72.2 Differential Diagnosis of Immune Thrombocytopenia (ITP)

Falsely Low Platelet Count

- In vitro platelet clumping caused by EDTA-dependent or cold-dependent agglutinins, insufficiently anticoagulated specimen, glycoprotein IIb/IIIa inhibitors (e.g., abciximab)
- Giant platelets that are miscounted as WBC rather than platelets by automated counters

Common Causes of Thrombocytopenia

- Pregnancy (gestational thrombocytopenia, preeclampsia, HELLP syndrome)
- Drug-induced thrombocytopenia (common drugs include heparin, quinidine, quinine, sulfonamides, acetaminophen, cimetidine, ibuprofen, naproxen, ampicillin, piperacillin, vancomycin, linezolid, glycoprotein IIb/IIIa inhibitors)
- Viral infections such as HIV, HCV, EBV (infectious mononucleosis), rubella

Helicobacter pylori

- Malaria
- Hypersplenism caused by chronic liver disease
- Alcohol
- Nutrient deficiencies (e.g., vitamin B_{12}, folate, copper)
- Rheumatologic/autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis)

Other Causes of Thrombocytopenia Mistaken for ITP

- Myelodysplasia
- Congenital thrombocytopenias
- Thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome
- Chronic disseminated intravascular coagulation

Thrombocytopenia Associated With Other Disorders

- Autoimmune diseases, such as systemic lupus erythematosus
- Lymphoproliferative disorders (chronic lymphocytic leukemia, non-Hodgkin lymphoma)

EBV, Epstein-Barr virus; *EDTA,* ethylenediaminetetraacetic acid; *HCV,* hepatitis C virus; *HELLP,* hemolysis, elevated liver enzymes, and low platelet levels; *HIV,* human immunodeficiency virus; *WBC,* white blood cell.

Adapted from George JN, El-Harake MA, Raskob GE. Chronic idiopathic thrombocytopenic purpura. *N Engl J Med.* 1994;331:1207-1211.

ITP more commonly occurs in females, with bimodal age distribution peaking between 1 to 5 years old and >60 years of age.[6] The clinical manifestation of ITP in children is unique, with sudden-onset severe thrombocytopenia; complete spontaneous remissions are seen in approximately 80% of affected children.

Management of ITP depends primarily on the severity. Asymptomatic, low-risk patients with platelet counts higher than 30,000/mm^3 may be observed without further intervention. Platelet counts of 50,000/mm^3 and higher are rarely associated with clinical sequelae, even with invasive procedures. Initial medical treatment of patients with platelet counts below 30,000/mm^3 and symptoms such as mucous membrane bleeding, high-risk conditions (e.g., active lifestyle, hypertension, peptic ulcer disease), or platelet counts below 20,000 to 30,000/mm^3, even without symptoms, is glucocorticoid administration (prednisone 0.5–2 mg/kg/day or dexamethasone 50 mg/day for 4 days).[2] Clinical response with increases in platelet levels to higher than 50,000/mm^3 is seen in up to two-thirds of patients within 1 to 3 weeks of initiating treatment. Of patients treated with steroids, 25% will experience a complete response. Initial hospitalization for treatment may be required for patients with platelet counts <20,000/mm^3. Platelet transfusion is indicated only for those who experience severe hemorrhage. Intravenous immune globulin is important for the treatment of acute bleeding, in pregnancy, or for patients being prepared for operation, including splenectomy. This dose usually increases the platelet count within 3 days; it also increases the efficacy of platelet transfusions.

In adults with ITP who are corticosteroid dependent or corticosteroid unresponsive, second-line therapy may include rituximab (375 mg/m^2/week intravenously for 4 weeks), thrombopoietin receptor antagonists (TPO-RAs; eltrombopag, romiplostim), or splenectomy. There are no clear guidelines for which second-line therapy is preferred, and the American Society of Hematology suggests that treatment should be individualized based on duration of ITP, frequency of bleeding episodes, comorbidities, age, social support, cost, and availability.[2] In a 2019 meta-analysis, aggregate response rates at 1 month for splenectomy, TPO-RA, and rituximab were 86.7%, 65.7%, and 62.1%, respectively.[2]

For patients with ITP less than 1 year, spontaneous remission may be possible, and secondary treatment with either TPO-RA or rituximab is generally preferred. However, for those patients who are corticosteroid unresponsive or dependent beyond 1 year, splenectomy should be considered. In the pediatric population, splenic preservation is preferred, and high rates of spontaneous remission are seen; therefore, medical therapy is recommended over splenectomy when feasible.[7] Splenectomy is also the treatment of choice for patients with incomplete response to glucocorticoid treatment and for pregnant females in the second trimester who have also failed to respond to steroid treatment or intravenous immune globulin therapy with platelet counts below 10,000/mm^3 without symptoms or below 30,000/mm^3 with bleeding problems.[8]

Splenectomy represents a desirable second-line treatment option for patients who value a durable medication-free response. Most patients will exhibit improved platelet counts within 10 days postoperatively, and durable platelet responses are associated with patients who have platelet counts of 150,000/mm^3 by postoperative day 3 or more than 500,000/mm^3 by postoperative day 10. Two large systematic reviews have reported response rates after splenectomy of 66% and 72%.[9,10] Careful evaluation for splenules should be undertaken, using both preoperative imaging and a systematic operative approach. In their evaluation of 394 patients treated with laparoscopic splenectomy, Katkhouda and colleagues noted 15% of patients with accessory spleens.[11] Retained accessory spleen should be considered in the differential diagnosis for refractory ITP after splenectomy. Workup may include radionucleotide scans, and resection should be considered for patients who are adequate surgical candidates.

Hereditary Anemias

Hereditary anemia is classified into (1) defects of the RBC membrane (e.g., HS); (2) defects in erythrocyte enzyme (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency); and (3) defects in hemoglobin synthesis (e.g., thalassemia, sickle cell anemias [hemoglobin S]).

The decision to perform splenectomy, particularly among patients with hemolytic disorders, needs to be individualized. The benefits of surgery need to be balanced against risk of overwhelming postsplenectomy infection syndrome (OPSI), arterial/venous thromboembolism, and pulmonary arterial hypertension.[12]

Hereditary Spherocytosis

HS is the third most common inherited anemia, following sickle cell disease and thalassemia, and results from an autosomal dominant or recessively inherited defect in the erythrocyte cell membrane. Mutations affecting the production of cytoskeleton proteins such as spectrin, ankyrin, band 3 (anion exchanger AE1), and band 4.2 lead to the loss of the usual biconcave erythrocyte shape.[13] These erythrocytes lack deformability, are more rigid, and have increased osmotic fragility, leading to trapping and destruction in the spleen. Clinically, HS presents with moderate hemolytic anemia, jaundice, folate deficiency, and splenomegaly. Diagnosis is made by hematologic workup, including peripheral blood smear demonstrating spherocytes, elevated lactate dehydrogenase, increased indirect bilirubin, absence of decreased haptoglobin, increased osmotic fragility, and negative Coombs test result.

Splenectomy is indicated in severe HS, when hemoglobin is <8 g/dL, and moderate HS, with hemoglobin 8 to 12 g/dL based on individual metrics, including spleen size and quality-of-life parameters.[12] Splenectomy should be delayed until 6 years to preserve immunologic function of the spleen and to reduce the risk of OPSI. Challenging clinical scenarios in HS remain, including the role for partial splenectomy below 6 years of age and the role for concurrent splenectomy and cholecystectomy, and are outside the scope of this review.

Hereditary elliptocytosis, hereditary pyropoikilocytosis, hereditary xerocytosis, and hereditary hydrocytosis also result in anemia secondary to RBC membrane abnormalities. Splenectomy may be indicated in cases of severe anemia with these conditions, except hereditary xerocytosis, which results in only mild anemia of limited clinical significance.[14]

Hemolytic Anemia Caused by Erythrocyte Enzyme Deficiency

PKD and G6PD deficiency are the predominant hereditary conditions associated with hemolytic anemia. PKD is an autosomal recessive disease, resulting in insufficient pyruvate to maintain RBC membrane structure and spleen-mediated RBC destruction. G6PD deficiency is an X-linked disease, resulting in a deficiency of nicotinamide adenine dinucleotide phosphate (NAPDH), high RBC susceptibly to oxidative stress, and episodic stress-related hemolysis. Splenectomy is indicated in patients with severe PKD, particularly among those with high transfusion requirements.[12] A recent international, multicenter registry suggested that splenectomy reduced transfusion in 91% of cases; however, transfusion dependency and moderate anemia persist in >50% of patients. These data suggest that the decision to perform splenectomy should be individualized based on burden of disease.[15] Similarly, splenectomy in G6PD deficiency should be considered in cases of symptomatic splenomegaly or transfusion dependence.

Hemoglobinopathies

Sickle cell disease and thalassemia are the two most clinically important inherited hemoglobinopathies and may necessitate splenectomy. Sickle cell disease is a point mutation in the β globin gene resulting in a single amino acid substitution (valine for glutamic acid) in the sixth position of the β chain of hemoglobin A. Sickle cell disease results from homozygous inheritance of the defective hemoglobin (hemoglobin S), although it can be seen when hemoglobin S is inherited along with other hemoglobin variants, such as hemoglobin C or sickle cell β-thalassemia. In African Americans, 8% are heterozygous for hemoglobin S (sickle cell trait) and approximately 0.5% are homozygous for hemoglobin S. The affected hemoglobin chains become rigid, sickle shaped, and unable to deform under reduced oxygen conditions. These misshapen cells are unable to pass through the microvasculature, resulting in capillary occlusion, thrombosis, and ultimately microinfarction, frequently in the spleen. These episodes of vasoocclusion and progressive infarction result in autosplenectomy. The thalassemias are a group of autosomal recessive disorders with a disproportional α-to-β chain ratio, resulting in precipitation of the unpaired chain and subsequent RBC destruction. Thalassemia is classified into two main types depending on which globin chain is defective: α-thalassemia and β-thalassemia. Splenomegaly, hypersplenism, and splenic infarction are commonly seen in patients with sickle cell disease and thalassemia.

Acute splenic sequestration crises are life-threatening disorders in children with sickle cell disease or sickle β-thalassemia. In this condition, there is a rapid drop in hemoglobin level because of vasoocclusion and splenic RBC sequestration, leading to life-threatening hypovolemic shock. Patients with acute splenic sequestration crisis present with severe anemia, abdominal pain, splenomegaly, and reticulocytosis. Treatment for acute splenic sequestration includes resuscitation, followed by consideration of splenectomy (in particular after two episodes), given high rates of recurrence and associated high mortality.[12,16]

Hypersplenism related to sickle cell disease is characterized by transfusion-dependent anemia, leukopenia, and thrombocytopenia. Splenectomy may be indicated in patients with sickle cell disease, with pressure effects caused by splenomegaly or failure to thrive. Despite being recommended in these scenarios, there is limited evidence demonstrating an improvement in hemoglobin levels or overall survival, which may be related to increases in thromboembolism.[12,16]

Splenic abscesses may also be seen in patients with sickle cell anemia. These patients present with fever; abdominal pain; and a tender, enlarged spleen. Most patients with splenic abscesses will present with leukocytosis, thrombocytosis, and Howell-Jolly bodies on peripheral smear, indicating a functional asplenia. *Salmonella* and *Enterobacter* spp. are common pathogens. These patients require resuscitation and antibiotics and may require urgent splenectomy after stabilization.

Malignant Disease

Hematopoietic Neoplasm

Lymphomas. Hodgkin lymphoma (HL) is a group of malignant conditions that are characterized by the presence of Reed-Sternberg cells. HL usually affects adults in their 20s and 30s with a second peak in adults over the age of 50. Rarely, patients present with constitutional symptoms such as night sweats, weight loss, and pruritus, but more typically, patients present with asymptomatic lymphadenopathy that usually involves the cervical nodes. Historically, splenectomy played a critical role in patients with HL and was part of a standard staging laparotomy. However, current staging is performed with cross-sectional imaging, and treatment includes radiation and chemotherapy, with splenectomy reserved for patients with symptomatic splenomegaly.

Non-Hodgkin lymphoma (NHL) is a group of malignant neoplasms derived from progenerates of B cells, T cells, mature B cells, and mature T cells. Splenomegaly is common in NHL and may present with cytopenia because of hypersplenism. Splenectomy is indicated for patients with symptomatic splenomegaly, which may present as abdominal pain, early satiety, and fullness. It may also be indicated for patients who develop refractory anemia, neutropenia, and thrombocytopenia associated with hypersplenism.

Splenectomy may also be indicated in the diagnosis and treatment of splenic marginal zone lymphoma, a subtype of NHL previously termed *splenic lymphoma.* This is a rare subtype of NHL, accounting for <1% of patients. Most present with splenomegaly, lymphocytosis, anemia, and thrombocytopenia.[17] Diagnosis of splenic marginal zone lymphoma is challenging and can definitively be made on splenic histology. If clinical suspicion is high for splenic marginal zone lymphoma, splenectomy may be indicated for diagnosis. Splenectomy is also indicated for symptomatic splenomegaly and with suspected large cell transformations on PET/CT scan. In patients with spleen-predominant disease, splenectomy may provide durable improvement in splenic sequestration and improve survival.[17]

Leukemia

Hairy cell leukemia. Hairy cell leukemia, accounting for approximately 2% of adult leukemias, is characterized by splenomegaly, pancytopenia, and neoplastic mononuclear cells in the peripheral blood and bone marrow with characteristic cytoplasmic projections. Typically indolent in course, hairy cell leukemia was historically treated with interferon and splenectomy. However, more recently purine analogues and targeted agents (rituximab and anti-BRAF therapy) represent the mainstay of medical therapy. Splenectomy may remain a valid treatment option for patients with splenomegaly and low bone marrow involvement, refractory/relapsed disease, splenic rupture, pregnancy, or transfusion-dependent splenic sequestration.[18]

Chronic lymphocytic leukemia. Chronic lymphocytic leukemia (CLL) is the most common leukemia in the Western world and is characterized by the progressive accumulation of relatively morphologically normal, mature, but functionally incompetent lymphocytes. Low-risk CLL (formerly stage 0) involves bone marrow and blood lymphocytosis only; intermediate-risk CLL (formerly stages I and II) involves lymphocytosis and lymphadenopathy in any site or splenomegaly, hepatomegaly, or hepatosplenomegaly; and high-risk CLL (formerly stages III and IV) involves lymphocytosis and anemia or thrombocytopenia. Medical treatment is reserved for fit patients with symptomatic disease and advanced stages. Splenectomy is rarely indicated in CLL, aside from symptomatic splenomegaly or rare cases of splenic rupture.

Chronic myelogenous leukemia. Chronic myelogenous leukemia (CML) is a myeloproliferative disorder that develops as a result of a neoplastic transformation of myeloid elements. CML is characterized by the progressive replacement of normal diploid elements of the bone marrow with mature-appearing neoplastic myeloid cells. Although CML can be asymptomatic at presentation, patients commonly present with fever, fatigue, malaise, effects of pancytopenia (e.g., infections, anemia, easy bruising), and occasionally splenomegaly. Peripheral blood smear analysis shows leukocytosis of white blood cell count up to 100,000/μL. The gold standard for the diagnosis of CML is expression of the BCR-ABL fusion oncogene.

CML usually presents with an asymptomatic chronic phase but may progress to an accelerated phase associated with fever, night sweats, and progressive splenomegaly and a blastic phase characterized by anemia, opportunistic infections, and bleeding.

Targeted therapy with kinase inhibitors, cytotoxic chemotherapy, and bone marrow transplant is used in treatment of CML. Symptomatic splenomegaly and hypersplenism in CML can be effectively treated with splenectomy, but there does not appear to be a survival benefit when it is performed during the early chronic phase. Surgery is ultimately reserved for patients with symptomatic splenomegaly or hypersplenism.

Nonhematologic Tumors of the Spleen

Although lymphoma is the most common primary tumor of the spleen, other splenic lesions are common and can typically be differentiated based on imaging characteristics and clinical presentation. Hemangiomas are frequently incidentally identified on cross-sectional imaging and have been identified in up to 14% of patients at autopsy.[19] The natural course of hemangiomas is indolent, and rupture, hypersplenism, and malignant degeneration are rare and occur late in the course. Hemangiosarcomas are typically <2 cm, round, and have immediate homogenous enhancement on CT. They are rare and may be related to environmental exposure; they are also aggressive and associated with poor prognosis.

Inflammatory myofibroblastic tumor (IMF), previously known as *inflammatory pseudotumor,* is uncommon and potentially linked to Epstein-Barr virus exposure. These lesions are typically large (>10 cm), with characteristic central stellate calcifications on imaging, and are composed of inflammatory and myofibroblastic spindle cells.[20] These tumors have intermediate malignant potential and should be resected.

Lymphangiomas, most commonly seen in children, are endothelium-lined cysts that can lead to splenomegaly secondary to cyst enlargement. These are usually benign tumors; however, malignant degeneration is rarely possible. Imaging typically identifies thin septa within a multiloculated cyst. Splenectomy is appropriate for symptomatic lesions.[21]

Additional rare benign and borderline malignant splenic lesions may be seen. Splenic sarcoidosis is present in up to 40% of patients with systemic disease and may portend poorer prognosis. Litoral cell angioma is a rare vascular tumor that results in splenomegaly and may be associated with autoimmune conditions. If suspected, splenectomy is indicated for diagnosis and treatment. Sclerosing angiomatoid nodular transformation is another rare vascular tumor, typically mistaken for IMF on imaging; splenectomy is effective, with no reported recurrences. Splenic hamartomas are also rare and challenging to identify on imaging and are usually identified after diagnostic splenectomy on pathology.

Secondary metastatic splenic neoplasms are rare and thought to be the result of a lack of afferent lymphatics and are seen in up to 7% of autopsies of patients with cancer. The most common primary tumors for splenic metastases are breast, lung, and melanoma. Splenectomy may be considered in appropriate surgical candidates, with symptomatic or solitary lesions.

Miscellaneous Benign Conditions

Splenic Cysts

Splenic cysts have been seen with increasing frequency since the advent of CT and ultrasound scanning. They are classified as parasitic and nonparasitic cysts. The nonparasitic cysts are further divided into true cysts and pseudocysts. True cysts are lined with epithelium and may be considered congenital and account for 10% of all splenic cysts.

Parasitic cysts occur in areas of endemic hydatid disease (*Echinococcus* spp.). Radiographic imaging, usually with ultrasound, reveals cyst wall calcifications or daughter cysts, and although hydatid disease is uncommon in North America, this diagnosis must be excluded before invasive procedures are undertaken that might result in spillage of the cyst contents. Rupture of the cyst and expulsion of contents into the abdomen may precipitate anaphylactic shock and intraperitoneal infection. Serologic testing is helpful for verifying the presence of these parasites. Splenectomy is the treatment of choice. As with hydatid cysts of the liver, the cysts may be sterilized by injection of a 3% sodium chloride solution, alcohol, or 0.5% silver nitrate.

Nonparasitic true cysts of the spleen account for approximately 10% of all splenic cysts. These epithelial cells are often positive for carbohydrate antigen 19-9 and carcinoembryonic antigen by immunohistochemistry. Patients with splenic epidermoid cysts may have elevated serum levels of one or both of these tumor markers. These cysts, however, are benign and are often asymptomatic and discovered incidentally. Patients may complain of abdominal fullness, early satiety, pleuritic chest pain, shortness of breath, and left shoulder or back pain. On physical examination, an abdominal mass may be palpable. Rarely, splenic cysts present with acute symptoms related to rupture, hemorrhage, or infection. Diagnosis is best made by CT, and operative intervention is indicated for those with symptomatic or large cysts. Total or partial splenectomy may provide appropriate treatment.

Nonparasitic pseudocysts represent the remaining 70% to 80% of splenic cysts. A history of prior trauma can typically be elicited. Pseudocysts of the spleen are not lined with epithelium. Radiologic imaging usually reveals a smooth, unilocular, thick-walled lesion, sometimes with focal calcifications. Asymptomatic, small (<4 cm) pseudocysts do not require treatment and may involute with time. Symptomatic pseudocysts are treated surgically with total or partial splenectomy. Percutaneous drainage has also been reported for splenic pseudocysts, although this has higher recurrence and should generally be reserved for poor surgical candidates.

Splenic Abscess

Splenic abscess is an unusual but potentially life-threatening illness if not promptly identified and treated, with mortality rates from 15% to 20% in immunocompetent patients and up to 80% in immunocompromised patients. Malignancy, polycythemia vera, endocarditis, prior trauma, hemoglobinopathies, urinary tract infections, intravenous drug use, and acquired immunodeficiency syndrome may preclude patients to develop abscesses.

Approximately 70% of splenic abscesses result from hematogenous spread of the infective organism, typically from endocarditis, osteomyelitis, and intravenous drug use. Spread may also occur in a contiguous fashion from local infections of the colon, kidney, or pancreas. Gram-positive cocci (commonly *Staphylococcus, Streptococcus,* or *Enterococcus* spp.) and gram-negative enteric organisms are common. *Mycobacterium tuberculosis, Mycobacterium avium, Actinomyces,* and fungal abscesses have also been described, typically in immunosuppressed patients.

Splenic abscesses present with nonspecific symptoms: vague abdominal pain, fever, peritonitis, and pleuritic chest pain. Splenomegaly is not typical. CT is the preferred method for diagnosis. Treatment of splenic abscesses depends on whether the abscess is unilocular or multilocular. Unilocular abscesses are often amenable to percutaneous drainage, along with antibiotics, with high success rates. Multilocular lesions, however, are usually treated with splenectomy, drainage of the left upper quadrant, and antibiotics.

Wandering Spleen

Wandering spleen is a rare finding, seen in children and in females between the ages of 20 and 40 years. Wandering spleen may be related to failure of normal embryologic attachments to form or hormonal changes leading to laxity in splenic ligaments. Without typical attachments, the splenic pedicle is unusually long and prone to torsion.

Intermittent abdominal pain, splenomegaly from venous congestion, and severe abdominal pain are suggestive of wandering spleen caused by intermittent torsion of the splenic pedicle. A mobile mass may be palpable on physical examination. CT provides confirmation of the diagnosis, with the spleen located outside its usual position. A noncontrasted spleen or whorled appearance of the vascular pedicle provides additional evidence for the condition and may be helpful in choosing splenopexy or splenectomy.

Other Considerations

Splenic Trauma

Vascular conditions. Splenectomy could be indicated for vascular conditions that will be discussed elsewhere in this textbook. These vascular disorders are portal hypertension (see Chapter 51), splenic artery aneurysm (see Chapter 105), and splenic vein thrombosis.

Preoperative Considerations

As part of preoperative planning, several factors should be considered before deciding on the optimal operative approach (Box 72.3). In general, in patients who have sustained blunt trauma who either fail nonoperative/embolization management or are hemodynamically unstable at presentation, open splenectomy is still the standard of care.[22] Most other indications, including malignancy and massive splenomegaly, are still recommended to be attempted minimally invasively, with a hand-assist option as an available modification.[23,24] Diagnostic adjuncts such as CT or MRI are useful in operative planning and counseling the patient, specifically in determining splenic size/volume, potential accessory spleens, and presence of varices, and it is important to be prepared to change approach when the situation requires.[25]

Apart from surgical approach, preoperative medical optimization must also be considered. Specifically, as discussed in the earlier sections, for patients with ITP or hemolytic anemias such as thalassemia or sickle cell, discussion with the patient's hematologist

BOX 72.3 Preoperative Considerations for Operative Approach

Consideration	Variable
Indication for splenectomy[27]	Benign Malignant Trauma/emergency
Spleen size[28,29]	≥19 centimeters
Spleen volume[29]	≥1000 grams
Patient factors[25]	Previous abdominal surgery Patient obesity Potential contraindications to pneumoperitoneum Surgeon experience
Disease/anatomic factors[25]	Presence (or suspicion) of accessory spleens Presence of portal hypertension

should address expected need for blood product transfusions, steroid administration and/or tapering, and other treatments such as immunoglobulins.[26]

Laparoscopic Splenectomy

As with a majority of organ resections, a minimally invasive approach to splenectomy is the preferred method for resecting the spleen. The laparoscopic technique was first described in 1991,[24] and many studies have supported its use, with favorable outcomes and patient safety. Compared with an open surgical approach, potential disadvantages of the laparoscopic technique may be longer relative operating times and increased difficulty removing large spleens; however, the well-described benefits of reduced length of hospital stay (and hospital costs by proxy) and decreased morbidity and mortality more than justify these relative limitations.[30]

Most splenectomies can be safely completed minimally invasively, though the reported conversion rate to open surgery is between 0% and 20%.[31] Risk factors associated with conversion to open surgery include intraoperative hemorrhage, lack of surgical experience, significant intraabdominal adhesions, massive splenomegaly, and obesity.[32] As with other minimally invasive procedures, there is a learning curve, and with increasing experience, conversion to open splenectomy declines.[31]

In previously published investigations, laparoscopic outcomes and safety are considered equivalent to those of open splenectomy. Although older literature suggests open splenectomy should be used in cases of malignancy, newer data report similar oncologic outcomes with shorter length of stay, lower morbidity, and lower 30-day mortality, similar to outcomes reported for benign disease.[27,33]

Minimally invasive splenectomy should still be carefully considered, even in special populations. Portal hypertension with associated risk of uncontrollable operative hemorrhage was previously considered to be a relative contraindication for minimally invasive splenectomy. However, with advancement in laparoscopic techniques and improvements in laparoscopic energy devices and staplers, laparoscopic splenectomy can be safely performed in patients with portal hypertension.

Patient positioning. The laparoscopic technique may be performed in the lateral or supine position, depending on surgeon's preference, concomitant surgery, and patient's body habitus. The lateral technique is the most commonly used position. For all positions, the patient is placed on the operating table so that the kidney rest can be raised to maximize the space between the iliac crest and costal margin. The patient is tilted in a reverse Trendelenburg position to facilitate retraction of the viscera caudally away from the left upper quadrant.

In the right lateral decubitus position (Fig. 72.7), the patient is placed in a 60-degree right-side-down position using a beanbag

and axillary roll. In this case, the patient's left arm is placed on an arm board or supported by a splint with protection of all pressure points. With this approach, the surgeon and scrub technologist stand to the patient's right and the surgical assistants stand to the patient's left.[34] The spleen will then be allowed to suspend from its diaphragmatic attachments, and this allows gravity to retract the stomach, omentum, and colon. Additionally, the splenic hilum will be under some tension, which allows for ease of dissection. Alternatively, in the supine position, the surgeon stands to the patient's left, and the first assistant and camera assistant stand to the patient's right. For right-handed surgeons, it may be more ergonomic to stand between the patient's legs, which may be done either in lithotomy position or with the use of a split-leg table. The scrub technologist stands to the patient's left side, near the foot of the table.

Trocar placement. Initial entry into the abdomen is accessed with an open Hasson, Optiview, or Veress needle technique, medial to the left anterior axillary line, approximately 2 to 3 cm below the costal margin. Three to four additional ports are placed to triangulate the working area.

Surgical technique. Under direct laparoscopic visualization, the operation is begun with a thorough exploration of the abdominal cavity for the presence of accessory splenic tissue (Fig. 72.8). The stomach is retracted to the patient's right side to facilitate examination of the gastrosplenic ligament. The splenocolic ligament, greater omentum, phrenosplenic ligament, small and large bowel mesenteries, pelvis, adnexal structures, gastrosplenic ligament, and tail of the pancreas are carefully examined and confirmed to be free of splenic tissue (see Fig. 72.8). The critical steps of the laparoscopic splenectomy are summarized in Box 72.4 (Fig. 72.9).

(From Gigot JF, Lengele B, Gianello P, et al. Present status of laparoscopic splenectomy for hematologic diseases: certitudes and unresolved issues. *Semin Laparosc Surg*. 1998;5:147-167.)

Robotic Splenectomy

With increased access to and surgeon comfort with using robotic technology, many operations that have been traditionally performed laparoscopically are increasingly performed robotically. As surgeons and operative teams become more facile with robotic surgery, the ergonomic improvement, three-dimensional visualization, and increased range of motion advantages of a robotic approach over a laparoscopic approach for many procedures have become attractive.[35] Longer operating times and higher operative costs remain the most commonly documented disadvantages to robotic surgery in general, but with increased robotic use, these disadvantages are less prominent.[36] Few studies have specifically compared the two minimally invasive techniques for splenectomy. In a recent retrospective cohort study by Cavaliere and colleagues, robotic splenectomy in cases of splenomegaly was associated with decreased blood loss and longer operative times but otherwise comparable perioperative outcomes.[37] In another study, Bodner and colleagues compared operative times, hospital stay, and cost.[38] The study concluded that although the robotic procedure is feasible and safe for the patient, cost and operative times are both higher in the robotic group, which should be considered when planning for an operative approach. An area in which robotic splenectomy is likely to be most preferred is when in conjunction with distal pancreatectomy, especially in the malignant setting, where the robotic approach has been associated with higher regional lymph node yield and lower conversion to open rate.[39]

Short-Term Complications After Splenectomy

Splenectomy, like any other surgical procedure, is associated with risk of postoperative complications, regardless of the surgical

BOX 72.4 Critical Steps of Laparoscopic Splenectomy

1. Position patient in right lateral decubitus with operating table flexed to 45 degrees
2. Mobilize splenic flexure of the colon
3. Incise lateral peritoneal attachments to the spleen (tip: leave ~1cm of peritoneal cuff along the lateral spleen to facilitate grasping and retracting; see Fig. 72.9)
4. Enter lesser sac along medial border of spleen
5. Visualize short gastric vessels, main splenic vascular pedicle, and tail of the pancreas
6. Ligate and divide short gastric vessels with laparoscopic energy device
7. Circumferentially dissect splenic vascular pedicle near the hilum and ligate and divide with laparoscopic stapler, avoiding injury to tail of the pancreas
8. Divide final splenophrenic attachments at the superior pole and place in laparoscopic retrieval bag
9. Remove spleen by morcellating (benign only) and remove through an enlarged port site (see Fig. 57.9; for malignant disease, spleen must be extracted intact through an appropriate incision)
10. Avoid spillage of any splenic tissue into the abdominal cavity

approach. In the immediate postoperative period, intraabdominal hemorrhage as a result of slipped ligature from the hilar vessels or other small vascular tributaries is one of the most common complications. Other well-described short-term complications include pneumonia, left-sided pleural effusion, colon injury, and pancreatic fistula from unrecognized pancreatic tail injury during splenic hilum dissection.[28,40] Pancreatic fistula, which may clinically manifest with abdominal pain, early satiety, fever, and leukocytosis with left shift is typically managed with percutaneous drainage. These must be managed appropriately in order to avoid infection and pseudoaneurysm with bleeding. Another important, yet rare, complication is gastric perforation at the greater curvature of the stomach, caused by iatrogenic injury to the greater curvature during dissection of the short gastric arteries. This commonly requires reoperation and may lead to chronic fistula if associated with concomitant pancreatic injury. Venous thromboembolism is another serious complication after splenectomy. It is thought to be related to reactive thrombocytosis after splenectomy; however, the correlation is not entirely clear. Abdominal venous thrombosis, also known as *postsplenectomy thrombosis of the splenic, mesenteric, and portal veins*, has an incidence of 8% to 10%, with splenic size and myeloproliferative disorder reported to be the main risk factors.[41,42] Presentation is usually with nonspecific postoperative gastrointestinal symptoms of abdominal pain and ascites. Management is typically nonsurgical with administration of systemic anticoagulation. Currently there is an increasing role for interventional radiology with catheter-based thrombolysis, stents, and/or thrombectomy.[43]

Late Morbidity After Splenectomy

Postsplenectomy thrombocytosis occurs most commonly in patients with myeloproliferative disorders (e.g., CML, polycythemia vera, essential thrombocytosis), which can result in thrombosis of the mesenteric, portal, and renal veins and can be life-threatening, leading to both risk of hemorrhage and thromboembolism. The risk for deep venous thrombosis and pulmonary embolism caused

BOX 72.5 Overwhelming Postsplenectomy Infection: Associated Risk Factors

- Young age
- Thalassemia major (8.2%)
- Sickle cell anemia (7.3%)
- Idiopathic thrombocytopenia (2.1%)
- Lymphoma
- Immunosuppression

Hashimoto N. Management of overwhelming postsplenectomy infection syndrome. *Clin Surg.* 2016;1:1148.

by platelet aggregation after splenectomy is estimated to be between 10% and 35%, and early aspirin administration in patients with marked thrombocytosis should be considered.[44,45]

OPSI is the most significant fatal late complication after splenectomy. Infection may occur at any time after splenectomy, but many studies suggest most severe infections occur more than 2 years after surgery. The reported mortality of OPSI is between 40% and 50%.[46] The risk is greatest in patients with thalassemia major and sickle cell disease (Box 72.5). OPSI is typically caused by polysaccharide-encapsulated organisms, such as *S. pneumoniae, N. meningitidis,* and *H. influenzae. S. pneumoniae* is estimated to be responsible for between 50% and 90% of cases.

Clinical presentation usually begins with flulike symptoms characterized by fever, rigors, chills, and other nonspecific symptoms, including sore throat, malaise, myalgias, diarrhea, and vomiting. These symptoms quickly progress to fulminant infection with multiorgan system failure, with the development of hypotension, disseminated intravascular coagulation, respiratory distress, coma, and death within a few hours to a few days of presentation.[47] Survivors of OPSI often have a long and complicated hospital course with multiple sequelae, such as peripheral gangrene requiring amputation, deafness from meningitis, mastoid osteomyelitis, bacterial endocarditis, and cardiac valvular destruction.[47]

Immunization

The immunization recommendations and formulations differ depending on the patient's age and region. Currently, the standard of care for asplenic and hyposplenic patients includes immunization with the 13-valent pneumococcal conjugate vaccine (PCV13) followed by the 23-valent pneumococcal polysaccharide vaccine (PPSV23) at least 8 weeks later, *H. influenzae* type b conjugate, the quadrivalent meningococcal conjugate ACWY vaccine series (MenACWY), and the monovalent meningococcal serogroup B vaccine series (MenB-4C or MenB-FHbp). In addition, all asplenic or hyposplenic patients should receive seasonal influenza vaccination; measles, mumps, and rubella (MMR); varicella; and tetanus diphtheria pertussis. Visit the US Centers for Disease Control and Prevention (CDC) website for details.[48] Ideally in an elective setting, these vaccines should be given at least 14 days before surgery. If the patient did not receive vaccines before surgery in instances of emergent operation, vaccines should be given 14 days after splenectomy or upon discharge (to improve compliance). In patients with functional asplenia or hyposplenism, vaccines should be given as soon it is recognized (Table 72.1).[47]

The CDC has concluded that despite physician and patient education, pamphlets, and MedicAlert bracelets, patients' retention regarding the risks of postsplenectomy sepsis is poor. The CDC recommends that all postsplenectomy patients, including those with HS, be revaccinated and reeducated between 2 and 6 years after splenectomy. Recommendations include determination of pneumococcal antibody titers after immunization, as nonresponders to vaccination may be at high risk for OPSI. Subsequent follow-up of antibody titers is recommended at 3 to 5 years to evaluate for possible need for revaccination.

Communication and educational efforts for primary care providers who assume medical care for asplenic patients are also extremely important because OPSI is preventable if appropriate

TABLE 72.1 Centers for Disease Control and Prevention Vaccine Recommendations for Asplenic Patients[a,b]

	PNEUMOCOCCAL VACCINATION	MENINGOCOCCAL VACCINATION	*HAEMOPHILUS INFLUENZAE* TYPE B VACCINATION
Children	Immunologically naïve 2–6 years[c]: PCV13 followed by PVC13 8 weeks later; PPSV23 8 weeks later; repeat PPSV23 at 5 years Immunologically naïve 6–18 years[c]: PCV13 followed by PPSV23 8 weeks later; repeat PPSV23 at 5 years	MenACWY series AND MenB series[d]	Hib once if 15 months or older and previously not vaccinated
Adults (age 19 and older)	Immunologically naïve[c]: PCV13 followed by PPSV23 8 weeks later; repeat PPSV23 every 5 years	MenACWY or MPSV4 2 months apart; repeat MenACWY every 5 years AND MenB series[d] once	Hib once

[a] First vaccination should be administered at least 2 weeks before splenectomy if elective.

[b] Even with vaccination, oral antibiotic prophylaxis with penicillin V or amoxicillin should be considered for children under 2 years of age or high-risk postsplenectomy patients.

[c] For patients who have previously received any PCV or PPSV23 or a combination of these vaccinations, the recommendations vary and are outlined in the CDC guidelines accessible online.

[d] MenB-4C 2 doses 1 month apart or MenB-FHbp 3 doses, 1 each at 0, 2, and 6 months.

Hib, H. influenzae type b; *MenACWY,* meningococcal 4-valent conjugate; *MPSV4,* meningococcal 4-valent polysaccharide; *PCV13,* 13-valent pneumococcal conjugate vaccine; *PPSV23,* pneumococcal 23-valent polysaccharide.

precautions are taken. CDC immunization guidelines for 2023 have recommended the following vaccines in addition to what has been discussed earlier for asplenic patients: tetanus (Tdap or Td), human papillomavirus (HPV), MMR, varicella, zoster, influenza, hepatitis A (hep A) and hepatitis B (hep B), and meningococcal.

Antibiotics

Significant controversy still exists about antibiotic prophylaxis in postsplenectomy patients. The primary goal of prophylaxis is to prevent OPSI, particularly secondary to pneumococcal infection, which is the most common cause of OPSI. However, OPSI secondary to penicillin-sensitive pneumococcal infection has been reported in children and adults receiving penicillin prophylaxis.

There are two general approaches for antibiotic prophylaxis in asplenic or hyposplenic patients. One is daily prophylactic dosing and the other is maintaining an emergency supply. There is variability of practice among different societies. For example, the Australian Spleen Society recommends daily antibiotic prophylaxis for children up to age 16 or a minimum up to age 5 or 3 years after splenectomy. In addition, they recommend lifelong prophylaxis for immunocompromised states and an emergency supply of oral antibiotics for postsplenectomy adults, with instructions to begin taking the medication at the onset of a febrile illness or rigors if there is no access to immediate medical evaluation.[49]

The oral antibiotic of choice is amoxycillin or oral penicillin. For patients with confirmed hypersensitivity or significant allergy, the second choice is a macrolide. For the emergency supply, we recommend the use of amoxycillin plus clavulanate, and for penicillin-allergic patients, macrolides or quinolones are acceptable alternatives.

There is evidence that the risk of OPSI is lowest in patients who exhibit the greatest understanding of the infectious risks of asplenia.[50] This highlights the importance of education of the patient, particularly at follow-up visits, to ensure compliance with antibiotic and vaccine prophylaxis. It is important to note any asplenic or hyposplenic patient who presents with rigors or fever, who must be started immediately on aggressive broad-spectrum empiric antibiotic coverage, even without culture data.

THYROID EMBRYOLOGY AND ANATOMY

Embryology

The thyroid gland originates from the median and lateral thyroid anlages—embryologic precursor tissues—which follow separate embryologic paths before fusing and forming a single gland.

Median Thyroid Anlage

In utero, thyroid development begins with the median thyroid anlage, which is a thickening of the endodermal epithelium of the foregut in the floor of the pharynx. This thickening becomes an outpouching of the endoderm adjacent to the myocardial cells. As it descends caudally, along with the myocardial cells, the median thyroid anlage becomes a bilobed diverticulum with a median tubal structure called the *thyroglossal duct,* which keeps the structure connected to the tongue. The thyroglossal duct becomes a solid structure in the fifth week, after which it fragments and disappears. The obliteration of this structure leaves the foramen cecum at the base of the tongue superiorly and, when present, the pyramidal lobe inferiorly. The thyroid continues to descend to its final position anterior to the trachea by the seventh week. The cells derived from the median thyroid anlage arrange to form follicles and produce thyroid hormone by the tenth week of gestation.

---

*Disclosure: JAS is a member of the Data Monitoring Committee of the Medullary Thyroid Cancer Consortium Registry supported by Novo Nordisk, Astra Zeneca, and Eli Lilly. Institutional research funding is received from Exelixis and Eli Lilly. TU has participated in research funded by Blueprint Pharmaceuticals.

Lateral Thyroid Anlage

The lateral thyroid anlage arises from the pharyngeal endoderm and fuses to the median anlage in the fifth week during its embryologic descent. The lateral thyroid anlage is comprised in part from cells of the ultimobranchial bodies, which originate from the fourth and fifth pharyngeal pouches. It is from these ultimobranchial bodies that the calcitonin-secreting parafollicular C cells arise. (The median anlage does not carry these cells.) The lateral thyroid anlage comprises approximately one-third of the total mass of the eventual thyroid gland.

Anomalies in the embryologic development of the thyroid gland can lead to a variety of conditions, some of which can be pathologic (Fig. 73.1).

Thyroglossal Duct Cyst

The normal development and subsequent obliteration of the thyroglossal duct are connected to that of the hyoid bone, which forms starting at the seventh week of gestation and functionally divides the thyroglossal tract into superior and inferior aspects. When the thyroglossal duct does not completely obliterate and the epithelial duct cells remain, a thyroglossal duct cyst may arise from a persistent connection between the thyroid gland and the foramen cecum. This scenario typically presents as a painless midline neck mass at or near the level of the hyoid, although it can be found near the base of the tongue or at the thyroid gland proper. These cysts can become infected from oral bacteria from the tongue and can also form fistulous sinuses to the skin. Occasionally, thyroid tissue can develop in remnants of the thyroglossal duct along its tract.

The Sistrunk procedure, originally described in 1920, is the surgical treatment of choice for thyroglossal duct cysts that become chronically infected. A number of modifications have been described, but the key component of the procedure involves excision of the entirety of the cyst and surrounding thyroglossal duct tract, including the central portion of the hyoid bone. Resection of a small portion of the tongue is no longer thought to be necessary in the majority of cases.

Ectopic Thyroid Tissue

Aberrant thyroid tissue can be found anywhere along the normal path of development and descent of the thyroid gland, from the foramen cecum down to the anterior mediastinum. The development of an undescended thyroid can lead to the formation of a lingual thyroid gland near the base of the foramen cecum. This abnormal thyroid tissue often is associated with inadequate thyroid hormone production with subsequent goitrous enlargement, which in turn can lead to local compressive symptoms of the upper neck, such as airway obstruction and dysphagia. Surgical excision is occasionally necessary for these cases.

The other common locations for ectopic thyroid tissue are along the path of the thyrothymic tract, which originates from the third pharyngeal pouch and pulls along the inferior parathyroid glands and lower poles of the thyroid lobes via the descending path of the thymus gland. Foci of normal thyroid tissue along this tract are typically referred to as *thyroid rests.* These rests can occur

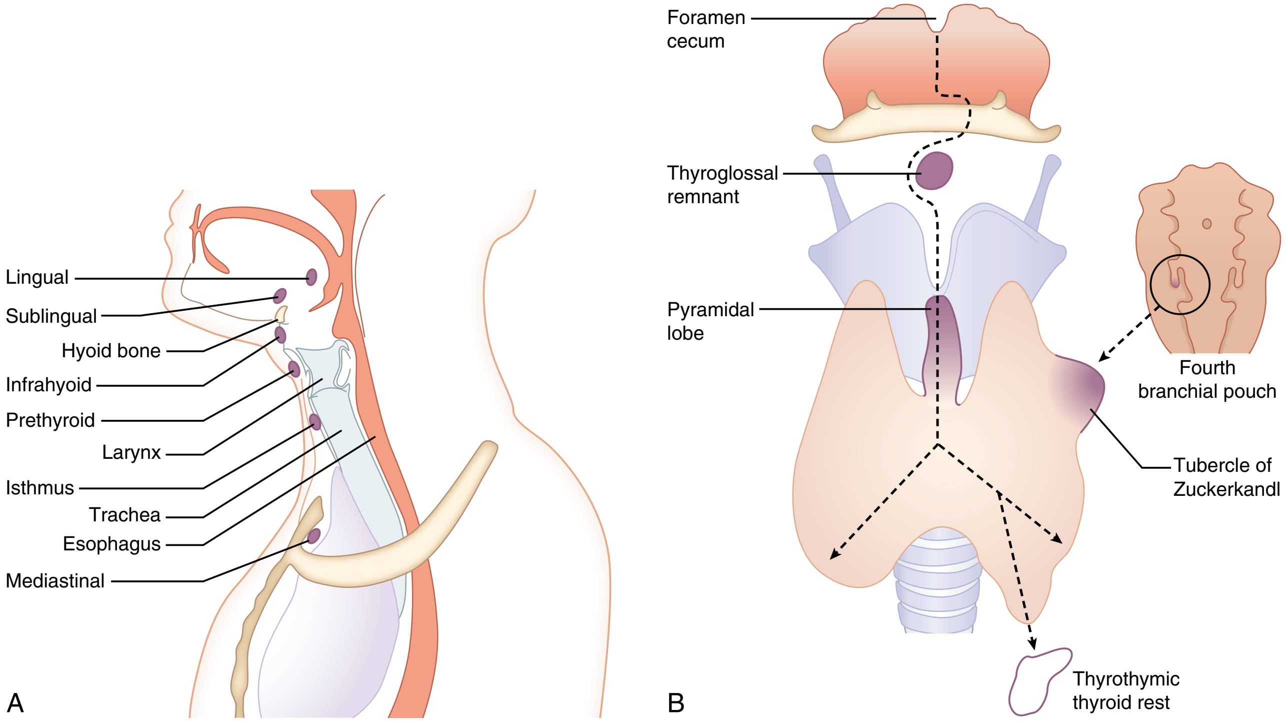

FIGURE 73.1 (A) Schema illustrating some common sites for midline ectopic thyroid masses. (B) A summary of the major medial and lateral embryologic elements of the thyroid gland and their potential adult anatomic consequences. (From Agarwal A, Mishra AK, Lomardi CP, et al. Applied embryology of the thyroid and parathyroid glands. In: Randolph GW, ed. *Surgery of the Thyroid and Parathyroid Glands.* 2nd ed. Philadelphia: Elsevier Saunders; 2013:18.)

in up to 50% of people and are typically not thought to be pathologic findings in and of themselves, although they occasionally may be mistaken for pathologic lymph nodes or parathyroid glands. Rests either can be connected to the thyroid gland proper by a thin stalk or can exist as completely separate structures. Primary intrathoracic goiters are thought to arise from enlargement of intrathoracic thyroid rests. Surgical treatment of thyroid rest tissue may occasionally be indicated if clinically relevant; examples of this include thyroid cancer requiring resection of a thyroid rest as a part of thyroidectomy or local compressive symptoms from an intrathoracic goiter. Another example of ectopic thyroid tissue is struma ovarii, which is a rare ovarian tumor with thyroid tissue comprising more than 50% of the overall mass. It is most commonly part of a teratoma and can be benign or malignant.

Anatomy

The normal thyroid gland is reddish-brown in color and rubbery in texture, with an adult gland typically weighing about 20 g. The thyroid gland typically is situated behind the sternohyoid and sternothyroid strap muscles and the superficial and middle layers of the deep cervical fascia.

When viewed in an anteroposterior plane, the shape of the thyroid resembles the silhouette of a butterfly, with two lateral lobes connected by an isthmus draped over the upper trachea just caudal to the cricoid cartilage. A normal-sized thyroid lobe is typically 4 to 6 cm in height and 1.3 to 1.8 cm in both transverse and anteroposterior dimensions. The isthmus typically has a thickness of 2 to 3 mm. In half to three-quarters of people, a pyramidal lobe extends superiorly from the isthmus and represents the caudal remnant of the thyroglossal duct. The right and left thyroid lobes make up the majority of the gland's volume. Each lobe's height extends from the level of the mid to upper aspect of the thyroid cartilage down to the fifth to sixth tracheal rings. Laterally, the lobe extends to the sternocleidomastoid muscle and carotid artery, with a small posterolateral projection or lump known as the *tubercle of Zuckerkandl.* The capsule enveloping the thyroid also forms separate "pseudolobules" within the parenchyma of the gland itself; these coalesce into a solid ligamentous structure at the posterolateral aspect of the upper trachea called the *suspensory ligament of Berry.* The tubercle of Zuckerkandl and Berry ligament are relatively constant anatomic landmarks for identification of the distal recurrent laryngeal nerve (RLN), which typically runs just posterior to these structures.

Blood and Lymphatic Supply

The thyroid is a highly vascular gland with abundant and redundant blood supply (Fig. 73.2). The arterial supply to the thyroid gland generally derives from two bilateral pairs of arteries. The superior thyroid arteries originate from the external carotid arteries and divide as they enter the superior poles of the thyroid lobes. The inferior thyroid arteries are branches from the thyrocervical trunks of the subclavian arteries. Because they branch fairly proximally from the thyrocervical trunk, their course runs cephalad and posterior to the carotid sheath before making a turn and entering the midthyroid lobes. In about 2% of people, a third artery called the thyroid ima artery arises directly from the aorta or innominate artery. This artery follows a midline path and enters the thyroid isthmus or the inferior poles of the thyroid lobes. The direction of the inferior thyroid artery as it enters the thyroid gland is another important landmark used for the identification of the RLN, which typically crosses the artery perpendicularly as it travels into the larynx (see later).

Branches of the inferior and superior arteries also supply the parathyroid glands. It is traditionally thought that the inferior thyroid arteries supply both superior and inferior parathyroid glands, but there can be significant anatomic variation around the arterial supply to the superior glands, which can be supplied by the inferior thyroid artery alone, the superior thyroid artery alone, or both.

There are three main venous drainage pathways from the thyroid gland. The superior thyroid veins typically run parallel to the superior thyroid arteries and drain into the internal jugular veins. The inferior thyroid veins run in a caudal direction from the inferior poles of the thyroid lobes and drain into the innominate veins. The middle thyroid veins are highly variable but typically arise from the lateral aspect of the midthyroid lobes; they drain into the internal jugular veins.

Much like the blood supply, the lymphatic network in and around the thyroid gland is rich and extensive. Lymphatic vessels course within the thyroid and drain into regional cervical lymph nodes. There is a standardized method and nomenclature for organizing the cervical lymph nodes into seven discrete "levels" (Fig. 73.3). An understanding of the pattern of lymphatic drainage from the thyroid is particularly important for understanding the surgical management of thyroid cancer (see "Thyroid Cancer" section later). The bulk of lymphatic drainage from the thyroid first goes to the perithyroidal lymph nodes in the central neck collectively grouped as level VI, which includes the lymph nodes

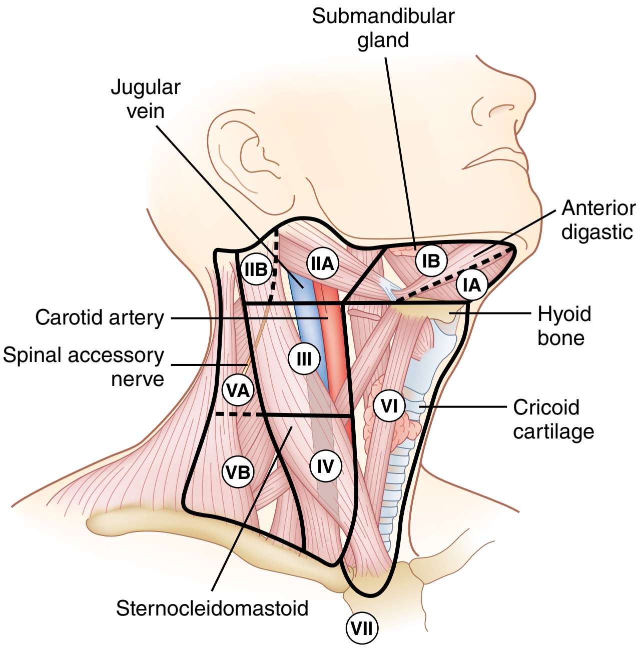

FIGURE 73.3 Lymph node compartments separated into levels and sublevels. Level VI contains the thyroid gland and the adjacent nodes bordered superiorly by the hyoid bone, inferiorly by the innominate (brachiocephalic) artery, and laterally on each side by the carotid sheaths. Level II, III, and IV nodes are arrayed along the jugular veins on each side, bordered anteromedially by level VI and laterally by the posterior border of the sternocleidomastoid muscle. Level III nodes are bounded superiorly by the level of the hyoid bone and inferiorly by the inferior aspect of the cricoid cartilage; levels II and IV are above and below level III, respectively. The level I node compartment includes the submental and submandibular nodes above the hyoid bone and anterior to the posterior edge of the submandibular gland. Level V nodes are in the posterior triangle, outside the lateral edge of the sternocleidomastoid muscle. Levels I, II, and V can be further subdivided as noted in the figure. The inferior extent of level VI is defined as the suprasternal notch. Many authors also include the pretracheal and paratracheal superior mediastinal lymph nodes above the level of the innominate artery (sometimes referred to as level VII) in central neck dissection.

between the two carotid arteries and bounded by the hyoid bone superiorly and the sternal notch inferiorly. This compartment extends inferiorly as level VII from the sternal notch to the brachiocephalic artery inferiorly. The lateral neck jugular lymph nodes (levels IIa, III, and IV) as well as those in the posterior triangle of the neck (particularly level Vb) also drain lymphatics from the thyroid, typically in transit from the central neck lymph nodes. Skip metastases that avoid level VI and extend directly from the primary tumor (typically in the superior pole of the thyroid) to the lateral neck are exceptional cases that occur in less than 15% of patients. Other levels of the neck are rarely associated with regional thyroid cancer metastases.

Nerves Associated With the Thyroid Gland

The thyroid is directly supplied by a network of tiny autonomic nerves arising from the superior and middle cervical sympathetic ganglia and parasympathetic fibers derived from the vagus nerve. The two most important nerves associated with the thyroid gland for the surgeon are the RLN and the external branch of the superior laryngeal nerve (EBSLN). It is critical that the thyroid surgeon have a thorough understanding of the normal and anomalous paths of these nerves, such that these structures can be better preserved during thyroidectomy.

The RLN and EBSLN are the main nerves responsible for the function of the larynx. Each nerve is paired, with a right and left side. The RLN is by far the more important nerve and innervates the motor function of all of the intrinsic laryngeal muscles except for the cricothyroid. It carries sensory fibers from the lower larynx as well as minor motor and sensory fibers from the trachea and esophagus. Unilateral injury to the RLN leads to paralysis of the ipsilateral vocal fold, with typical symptoms ranging from voice complaints such as hoarseness and vocal fatigue to aspiration. Bilateral RLN injury with subsequent bilateral vocal fold paralysis may require tracheostomy for airway control if the paralyzed vocal folds rest in a median position preventing adequate air exchange; alternatively, the risk of persistent aspiration and respiratory tract infections is high if the resting vocal folds remain in an abducted position. The EBSLN innervates the cricothyroid muscles, and it contributes to vocal fold tone and tension. EBSLN injury leads to difficulties with achieving high pitch and vocal projection and volume. The nerve became a historical focus of attention after the famous opera singer Amelita Galla-Curci developed difficulty singing high notes after thyroidectomy; this was thought to be because of injury to it during surgery, although subsequent historical reports dispute this claim.

The anatomy of the left and right RLNs differs based on their embryologic development (Fig. 73.4). Both RLNs are derived from the sixth branchial arches below the sixth aortic arches. As the fifth and sixth aortic arches above the RLNs subsequently regress in embryogenesis, the two nerves then anchor to, and follow, the right and left fourth aortic arch structures, which develop into differing arteries—the right subclavian artery and the aortic arch, respectively. Both nerves loop back, or “recur,” into the neck because of the heart and great vessels descending into the thorax, bringing the RLNs down with them. The left RLN loops under the ligamentum arteriosum at the aortic arch and travels in the tracheoesophageal groove until it reaches the thyroid. The right RLN loops under the right carotid-subclavian artery junction and migrates to the cricothyroid joint at the insertion into the larynx. Because of the lateral location of the right carotid-subclavian junction and the shorter length of the course of the right RLN, this nerve can be identified traveling in a slightly anterior plane and an oblique direction compared with the left RLN, which tends to stay relatively deep and straight in the tracheoesophageal groove.

There are a number of anatomic landmarks that can aid in identification and characterization of the RLN. The tubercle of Zuckerkandl typically lies just anterior and lateral to the nerve. There is an intimate relationship between the nerve, Berry ligament, and inferior thyroid artery at the level of the cricoid cartilage. Here, the nerve crosses the artery (usually posteriorly) and typically curves anteriorly toward the ligament before diving posteriorly again into the laryngeal insertion point at the cricothyroid joint. There are numerous anatomic variations of the course of the nerve and its relationship with the three structures, particularly with respect to how anteriorly the nerve can be positioned. In addition, the RLN may branch more proximally in up to 20% to 30% of cases, and preservation of all of the branches is important to preserve nerve function; this is particularly true for the anterior branches, which predominantly provide motor innervation.

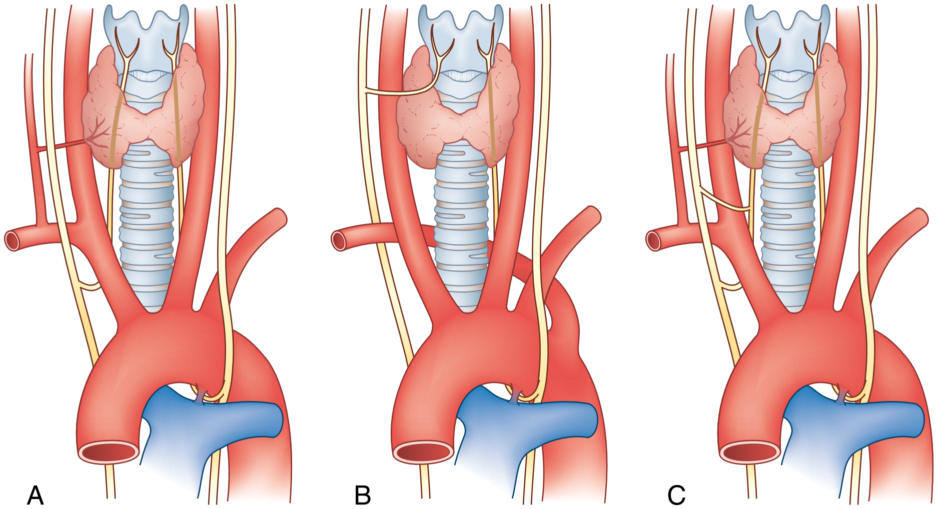

FIGURE 73.4 **Anomalous variations in the course of the right recurrent laryngeal nerve.** (A) The normal course of the recurrent laryngeal nerve arises from the vagus after it passes beneath the subclavian artery. A nonrecurrent laryngeal nerve arises from the vagus and courses medially into the larynx in the setting of an aberrant origin of the right subclavian artery. (B) A nonrecurrent laryngeal nerve arises from the vagus and courses medially into the larynx in the setting of an aberrant origin of the right subclavian artery. (C) The unusual coexistence of a nonrecurrent laryngeal nerve and the recurrent laryngeal nerve forms a common distal nerve.

The RLN also may course in a nonrecurrent fashion, instead branching in a direct path from the cervical vagus nerve (see Fig. 73.4). On the right side, this is associated with—and likely secondary to—an aberrant right subclavian artery arising directly from the aortic arch instead of the innominate artery (called the *lusoria artery*). This artery arises distal to the left subclavian artery and crosses the midline posterior to the esophagus. Because of the absence of a normal right subclavian-carotid junction to pull down the right RLN during embryologic development, the right RLN follows a straight path from the vagus nerve to the larynx. A right-sided non-RLN occurs in up to 1% of people. A left-sided nonrecurrent nerve can occur in the extremely rare scenarios of a patient with situs inversus and a right-sided aortic arch.

Like the RLN, the superior laryngeal nerve arises from the vagus nerve. The EBSLN branches off at the hyoid bone and runs along the inferior pharyngeal constrictor muscle before running parallel to the upper aspect of the superior pole thyroid vessels and then terminating in the cricothyroid muscle. Although the EBSLN is typically fairly high above the thyroid lobe, care must be taken when ligating and dividing the superior pole vessels during thyroidectomy because the anatomic variations in the EBSLN can run quite close to the vessels and the upper thyroid lobe and must be dissected away as the superior pole of the gland is taken down (Fig. 73.5).

THYROID HISTOLOGY AND PHYSIOLOGY

Histology

The thyroid is composed mainly of two epithelial cell types. The first and predominant type is the follicular cell, which is responsible for the production and secretion of thyroid hormone (Fig. 73.6). The second type is the parafollicular C cell, which secretes calcitonin. The histologic architecture of the thyroid is arranged into spherical follicles containing colloid. Colloid is made up of thyroglobulin (Tg), which is the noniodinated precursor to active thyroid hormone and acts as a reservoir. The parafollicular C cells are located within the interfollicular stroma and are mainly found in the lateral aspect of the mid and upper thyroid lobes.

Normal Thyroid Physiology

Thyroid Hormone

The synthesis of thyroid hormones is a complex multistep process that occurs within the thyroid follicle unit. The process is dependent on the presence of iodine and is outlined as follows:

- Follicular cells actively transport iodide anions across the cell membrane from the bloodstream into the cytoplasm via the Na/I symporter transmembrane protein. The concentration of iodine within the follicular cells is normally manyfold higher than that of the systemic circulation because of this active transport.
- Iodide then moves toward the follicular cell border with the colloid stores, and the anions are oxidized to form the neutral I_2 molecule. This form of iodine can pass through the cell membrane into the colloid.
- Colloid stores Tg, which contains a multitude of tyrosine residues. Colloid also contains the enzyme thyroid peroxidase (TPO), which catalyzes the next major step in thyroid hormone synthesis, which is the iodination of tyrosine residues on Tg. A tyrosine residue iodinated by a single iodine molecule leads to the formation of the molecule monoiodotyrosine and that iodinated by two iodine molecules leads to diiodotyrosine (DIT).
- The DIT and monoiodotyrosine molecules form covalent bonds with one another to constitute the active forms of thyroid hormone tetraiodothyronine, or thyroxine (T_4), formed by two DITs and carrying four iodine molecules, and triiodothyronine (T_3), formed by a DIT and monoiodotyrosine and carrying three iodine molecules. When stimulated

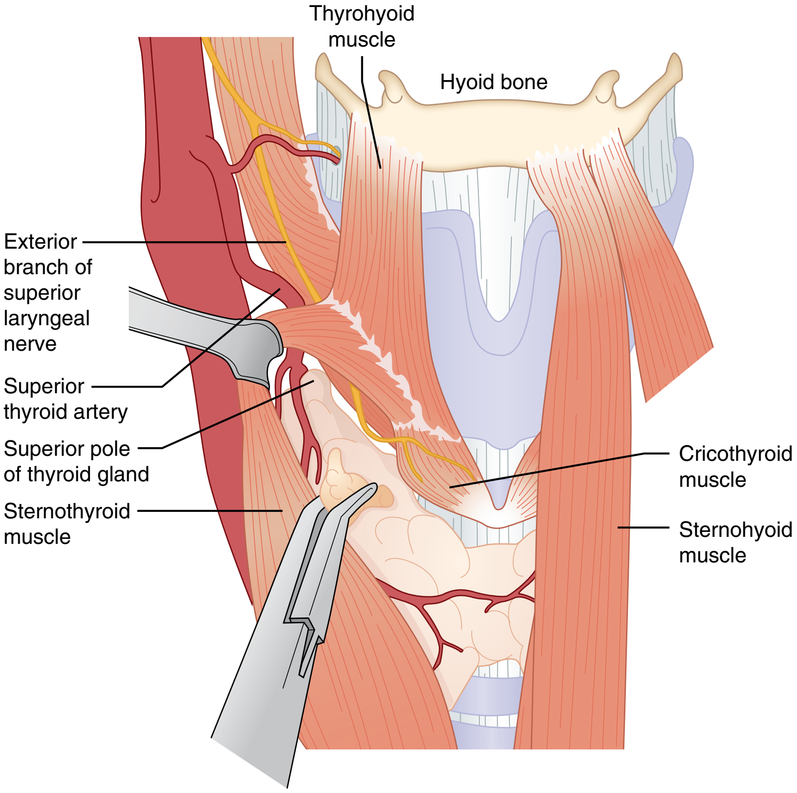

FIGURE 73.5 Dissection and ligation of the superior-pole thyroid vessels should be performed as far caudally on the thyroid gland as possible to avoid injury to the external branch of the superior laryngeal nerve. (From Randolph GW. Surgical anatomy, intraoperative neural monitoring, and operative management of the RLN and SLN. In: Duh QY, Clark OH, Kebebew E, eds. *Atlas of Endocrine Surgical Techniques*. Philadelphia: Elsevier Saunders; 2010:105.)

The parafollicular spaces contain blood vessels and parafollicular cells.

by thyroid-stimulating hormone (TSH), the follicular cells transport the activated thyroid hormones from the colloid center into the bloodstream (Fig. 73.7).

Once in the bloodstream, greater than 99% of circulating thyroid hormones are bound to transport proteins such as albumin and T_4-binding globulins; less than 1% exists in free form. This allows a relatively tight degree of control of thyroid hormone diffusion into target cells, in that the bound hormones will be released if circulating free levels decrease. Although there is normally a higher concentration of T_4 compared with T_3, T_3 is the more potent form, and in fact many target organs such as the brain, liver, gut, skeletal muscle, and thyroid are able to convert T_4 to T_3 through the deiodinase system that removes one of the iodine molecules.

Iodine plays a primary role in thyroid hormone physiology, and it is predicated on there being an adequate supply in the body. The average daily iodine requirement for adult humans is 0.1 mg, and this is entirely derived from dietary intake. The thyroid is the target for the overwhelming majority of the body's iodine stores. Seafood such as fish, shrimp, and seaweed are rich in iodine stores. Since 1924, the United States has iodized salt, which effectively has eliminated iodine deficiency in this country. Many regions of the world remain at risk for iodine deficiency despite worldwide efforts to improve access to iodized salt; the World Health Organization estimates that 54 countries remain iodine deficient.

Thyroid hormone is critical for normal bodily function. On a cellular level, T_4 and T_3 bind to mitochondrial receptors, leading to increased adenosine triphosphate (ATP) production, oxygen consumption, and glucose oxidation in a calorigenic process that releases heat. Therefore, thyroid hormone function is often referred to in shorthand as the primary driver of the basal metabolic rate. It is hypothesized that virtually all cells in the body are end-targets for thyroid hormone, mostly through their actions with

FIGURE 73.7 Cellular and molecular events involved in thyroid hormone function. Thyroxine *(T_4)* is converted in the periphery and in the cytoplasm of the cell into triiodothyronine *(T_3)*. T_3 travels to the nucleus, where it binds to a thyroid hormone receptor *(TR)* (homodimer, monomer, or heterodimer). TR binding leads to RNA transcription in association with other transcription factors; messenger RNA is subsequently expressed and then translated into protein.

regard to stimulating lipid and carbohydrate metabolism. Thyroid hormone is critical for normal in utero and childhood growth and development, especially with respect to neurologic function. The cardiovascular system is an important target of thyroid hormone, which increases cardiac output and vasodilatation. Normal reproductive function is highly dependent on thyroid hormone (see later).

The regulation of thyroid hormone production is tightly controlled by interactions between the hypothalamus, pituitary, and thyroid glands. Low circulating levels of T_4 and T_3 stimulate the hypothalamus to release thyrotropin-releasing hormone, which in turn stimulates the release of TSH from the anterior pituitary. TSH stimulates the formation of thyroid hormones by binding to its receptor on the thyroid follicular cells, leading to both increased transport of iodine and transport and release of T_4 and T_3 from the colloid into the bloodstream. Conversely, elevated circulating thyroid hormone levels lead to a negative feedback loop, with downregulation of thyrotropin-releasing hormone and TSH from the hypothalamus and pituitary, respectively.

Calcitonin

The thyroid gland also produces calcitonin from the parafollicular C cells, but the production of calcitonin is not regulated by the same processes that govern that of thyroid hormone. The primary known function of calcitonin is to decrease the serum concentration of calcium through its end-effect actions on bone (increasing osteoblast and decreasing osteoclast activity), gut (decreasing calcium absorption), and kidney (increasing urinary calcium excretion), and its release is stimulated by elevated serum calcium levels. However, the absence of calcitonin does not lead to a noticeable change in calcium homeostasis—as it would for parathyroid hormone (PTH)—and so its ultimate importance for normal physiologic function remains poorly understood.

Thyroid Physiology in Pregnancy

Normal pregnancy induces significant changes in thyroid hormone function because of its critical importance for early fetal development. Although multiple fetal processes depend on thyroid hormone, including overall growth, metabolic regulation, and bone maturation, neuronal and brain development are the most critical, as evidenced by the finding of severe neurocognitive deficits in babies born to mothers with untreated hypothyroidism.

During the first trimester, maternal thyroid hormone production rises significantly, with total T_4 concentrations increasing up to 1.5 times that of the nonpregnant state. Although the details are not completely elucidated, it is thought that this rise is at least in part because of the rapidly increasing levels of human chorionic gonadotropin, which shares a common alpha subunit with TSH and acts as a TSH agonist. This can occasionally lead to a phenomenon known as *transient gestational thyrotoxicosis* occurring only in the first trimester and resolving spontaneously.

The rise in T_4 concentration is also accompanied by a concomitant increase in T_4-binding globulin concentration in the bloodstream, which results in greater binding of the circulating T_4 and relative stability in free T_4 levels. Because of the increased demands for thyroid hormone production, the daily recommended iodine intake during pregnancy also rises. Maternal T_4 is transported to the fetal circulation via specialized thyroid hormone transporters in the placenta.

Maternal thyroid hormone production increases and peaks during the first trimester of pregnancy and declines steadily afterward; this likely coincides with the development and early function of the fetal thyroid. Measurable levels of fetal thyroid hormone can be detected by the eleventh week of gestation, but maturation of the entire hypothalamic-pituitary-thyroid feedback axis does not occur until the mid-second trimester; thus, it is thought that properly regulated maternal thyroid function remains important at least until this stage.

Thyroid dysfunction is associated with adverse maternal and fetal outcomes. As a result, regular monitoring of thyroid function is a standard component of routine prenatal care. Hypothyroidism is the most common type of thyroid dysfunction in pregnancy, occurring in up to 0.5% of pregnant females. Iodine deficiency is the most common cause of hypothyroidism in iodine-deficient regions, whereas autoimmune thyroiditis is the most common cause in iodine-replete areas. Maternal hypothyroidism is associated with an increased risk of infertility and perinatal complications. Fetal/neonatal hypothyroidism from iodine deficiency leads to cretinism, a syndrome presenting with severe growth and cognitive deficits, deafness, and failure of sexual development. Hyperthyroidism, most commonly because of Graves disease, occurs in about 0.3% of pregnant females; left untreated, this leads to an increased risk of maternofetal complications, including miscarriage, preeclampsia, preterm delivery, and abruptio placentae.

Thyroid Physiology in Nonthyroidal Illness (Euthyroid Sick Syndrome)

Many acute and chronic nonthyroidal disease states can affect thyroid function measurement. This phenomenon, commonly called *euthyroid sick syndrome* or *nonthyroidal illness syndrome,* leads to the finding of abnormal thyroid function tests in the setting of nonthyroidal illness in a patient without preexisting thyroid disease. The most common finding is low serum T_3 concentrations, with decreases in T_4 also seen in more severe disease states. TSH concentrations remain relatively normal to slightly elevated, but not to the degree of true hypothyroidism. Patients do not exhibit any signs of clinical thyroid dysfunction.

The pathophysiology behind euthyroid sick syndrome remains poorly understood, although several theories exist. Some believe that conversion of T_4 to T_3 in the target tissues is impaired during nonthyroidal illness because of decreased activity of peripheral deiodinase enzymes (in particular, deiodinase type 2). Others have investigated the role of cytokines such as tumor necrosis factor-α, interleukin-1, and interleukin-6 in decreasing thyroid hormone production at the level of the thyroid follicular cell. Others hypothesize that the inhibition of thyroid hormone binding to various thyroid-binding proteins may lead to inaccurate measurement of true free hormone levels. Regardless of theory, it is generally believed that patients with this phenomenon are in fact euthyroid and do not have intrinsic thyroid dysfunction.

Common states associated with euthyroid sick syndrome in surgical patients include sepsis, fasting/starvation, trauma, thermal injury, and myocardial infarction. Many medications such as corticosteroids and amiodarone also can affect thyroid function measurement. There is no treatment for euthyroid sick syndrome other than treating the underlying condition, which resolves the thyroid function test abnormalities.

THYROID BIOMARKERS

Thyroid-Stimulating Hormone

TSH is a 28-kDa glycoprotein secreted from the anterior pituitary gland in a pulsatile fashion; it follows a circadian rhythm. Its actions on the TSH receptor and thyroid follicular cells as a part of the hypothalamic-pituitary-thyroid axis make it a primary regulatory driver of thyroid hormone secretion. Measurement of serum TSH is the most common and reliable test for screening for thyroid dysfunction. This is because the negative feedback loop from T_4 and T_3 onto pituitary TSH secretion follows a log-linear relationship, resulting in more significant changes in TSH concentrations relative to smaller changes in thyroid hormone levels.

TSH is currently measured using third- and fourth-generation ultrasensitive radioimmunoassays, with associated degrees of precision to less than 0.002 μIU/mL and sensitivity up to 97%. The currently accepted normal range of serum TSH for adults is 0.4 to 4.12 mIU/L, with minor variation depending on the specific assay used. TSH measurement is indicated as a part of evaluation of suspected thyroid dysfunction as well as for screening and surveillance in high-risk settings such as pregnancy. Despite its overall high yield as a screening test, TSH values should be interpreted with caution in a number of nonthyroidal health states that can affect its measurement, such as pregnancy, nonthyroidal illness (euthyroid sick syndrome), and medications such as glucocorticoids, furosemide, anticonvulsants, and metformin.

Tetraiodothyronine and Triiodothyronine

Serum measurement of T_4 and T_3 is an important confirmatory component in the evaluation of thyroid dysfunction. The vast majority of both thyroid hormones in systemic circulation are bound to plasma proteins such as T_4-binding globulins, with less than 0.2% of the hormones available in the free, biologically active states. Because of this, measurement of free T_4 and free T_3 levels are more accurate in reflecting thyroid function compared with measuring total hormone levels, which can be falsely affected by the presence of various circulating transporter proteins.

The measurement of TSH and free T_4 are the most commonly paired thyroid function tests because of their accurate interpretability in the majority of scenarios, including the diagnosis and treatment monitoring of thyroid dysfunction. Free T_3 is not as useful for the diagnosis of hypothyroidism, but it can be useful for the confirmation of other conditions such as hyperthyroidism and euthyroid sick syndrome. All forms of thyroid hormones are measured using modern competitive immunoassays, with mild variations in normal ranges depending on the method and manufacturer. Normal reference ranges are also age dependent, with different standards for pediatric and adult populations.

Thyroid Autoantibodies

The measurement of serum thyroid autoantibodies is useful in the diagnosis of various autoimmune thyroid diseases, although their variable sensitivities and specificities require caution in test interpretation. The three most commonly measured autoantibodies today are anti-TPO (TPOAb), anti-Tg (TgAb), and anti-TSH receptor (TRAb).

Measurement of TPOAb is the most accurate and commonly used screening test for autoimmune thyroiditis. TPOAb is positive in over 90% of patients with autoimmune thyroiditis as well as 80% of patients with Graves disease. However, it also has a false-positive rate of 10% to 15%. Measurement of TgAb is commonly performed, with 80% sensitivity for autoimmune thyroiditis and 30% sensitivity for Graves disease and a similar false-positive rate as TPOAb. Importantly, the presence of TgAb interferes with the interpretation of Tg measurement for the surveillance of differentiated thyroid cancer (DTC; see later). TPOAb is usually measured by ultrasensitive immunoradiometric assays; TgAb also can be measured with this method, although other techniques such as radioimmunoassays or enzyme-linked immunosorbent assays are also acceptable. These two tests are often ordered together and are generally readily available in most clinical laboratories.

Measurement of TRAb is typically reserved for diagnostic confirmation of Graves disease because it is positive in over 90% of patients with the diagnosis. TRAb measurement is typically performed in one of two ways: (1) a TSH receptor-binding inhibitory immunoglobulin bioassay, which detects immunoglobulins inhibiting the binding of TSH to the recombinant TSH receptor, and (2) a thyroid-stimulating immunoglobulin (TSI) bioassay, which more specifically detects the stimulatory subtype of TRAb that activates the TSH receptor on thyroid follicular cells. TSI measurement has been hypothesized to more closely correlate with the severity of active Graves disease. According to the 2016 American Thyroid Association (ATA) guidelines for hyperthyroidism, initial evaluation of thyrotoxicosis can include measurement of TRAb, determination of radioactive iodine (RAI) uptake, or measurement of thyroidal blood flow on ultrasonography. Thyrotoxicosis related to Graves disease will demonstrate elevated TRAb, elevated iodine uptake in the thyroid gland, and/or elevated thyroidal blood flow. In a study employing a theoretical model of 100,000 patients in a US-managed care system, using TRAb to diagnose Graves disease reduced costs and provided faster diagnosis.[1]

Thyroglobulin

Tg is a large, 660-kDa glycosylated protein that acts as a precursor protein for the active iodinated forms of thyroid hormone. Although the majority of Tg is stored in colloid within the thyroid follicles, a small amount of Tg escapes into the systemic circulation during the conversion process to T_4 and T_3 and is thus detectable in peripheral blood. Tg can be particularly elevated in patients with DTC, although with low diagnostic utility for routine measurement or before total thyroidectomy. On the other hand, postoperative serum Tg measurement after total thyroidectomy with RAI for DTC remains among the most sensitive cancer biomarkers in existence today, with the caveat that its accuracy depends on the absence of TgAb.

Current widely used immunoassay methods for Tg measurement include enzyme-linked immunosorbent assay, enzyme-multiplied immunoassay, fluorescence polarization immunoassay, and immunochemiluminometric assay. All of these immunoassay methods have made Tg measurement highly sensitive and specific, such that it is possible to detect Tg down to the 0.1 ng/mL level. For postoperative surveillance of DTC, the sensitivity of Tg measurement can be augmented further with TSH stimulation, either after withdrawal of thyroid hormone or after injection of recombinant human TSH (rhTSH). A stimulated Tg of more than 1 to 2 ng/mL is considered higher risk for persistent or recurrent disease in the postthyroidectomy setting.[2]

The accuracy of serum Tg testing is highly dependent on the absence of TgAb, which must be obtained at the same time. TgAb is present in 10% to 15% of the general population and can limit the interpretability of postoperative Tg measurement. Even in these scenarios, TgAb often can be used as a crude surrogate biomarker because autoantibodies can disappear over time after the successful treatment of thyroid cancer; in addition, an increase in TgAb levels can signify disease recurrence.[3] Newer Tg assays that employ mass spectrometry offer reasonable detection capability even in the presence of TgAb, with sensitivities down to 0.5 ng/mL, approaching those of the immunoassays.

Calcitonin

Calcitonin is a 32–amino acid protein secreted by the parafollicular C cells. Normally, serum calcitonin levels are highest in infancy, decline rapidly in early childhood, then remain relatively stable through adulthood (although absolute levels can fluctuate minute to minute). Calcitonin does not appear to play a significant role in calcium homeostasis despite its known mechanisms of action at the level of the bone, gut, and kidney. Serum calcitonin is the most sensitive biomarker for the detection and surveillance of medullary thyroid cancer (MTC), which is a malignancy of the parafollicular C cells. This test is performed in patients with—or family members at risk for—MTC or multiple endocrine neoplasia type 2 (MEN2; see later). There is controversy around the utility of measuring serum calcitonin as a routine screening test in the evaluation of a thyroid nodule.[4] Calcitonin is currently measured using a variety of methods, including radioimmunoassays, enzyme-linked immunosorbent assay, and immunochemiluminometric assay, with differing sensitivities, specificities, and reference ranges.

THYROID IMAGING

Neck Ultrasound

Neck ultrasonography is the preferred modality for routine radiographic evaluation of the thyroid gland because it offers the most accurate visualization of thyroid nodular disease and allows for the concomitant ability to perform percutaneous fine-needle aspiration (FNA) biopsy of thyroid lesions (see later). Neck ultrasound provides information about overall thyroid size and vascularity, presence and risk stratification of thyroid nodules, and presence of suspicious cervical lymphadenopathy; in addition, it can be used to localize parathyroid disease. Advantages of ultrasound include the fact that it is noninvasive and portable for the clinic and it is not associated with radiation exposure.

One potential disadvantage of neck ultrasound is that the study quality is highly dependent on having a skilled operator; this issue is amplified by practice- and institution-specific variations on what specialties perform ultrasound because radiologists, surgeons, pathologists, and medical endocrinologists all may be trained in its performance. Efforts to standardize the quality of neck ultrasound have included common ultrasound training and credentialing pathways regardless of specialty as well as standardized templates for neck ultrasound reporting.

The normal sonographic appearance of the thyroid is homogeneously echogenic with a uniform echotexture (Fig. 73.8). Pathologic findings on thyroid ultrasound are described in the appropriate sections next.

Nuclear Scintigraphy

Thyroid scintigraphy is performed using either technetium-99m pertechnetate or a radiolabeled iodine nuclide (typically ^{123}I or ^{131}I). Depending on the specific study, the tracer can be administered intravenously, orally, or via inhalation, and images are obtained anywhere from 30 minutes (for intravenous [IV] injection) to 24 hours (for oral administration) afterward. The thyroid normally displays symmetric uptake bilaterally. Nodular disease can be classified into whether there is increased focal uptake (the so-called "hot" nodule, Fig. 73.9) or not (the "cold" nodule). Classically, "hot" nodules in the setting of hyperthyroidism are thought

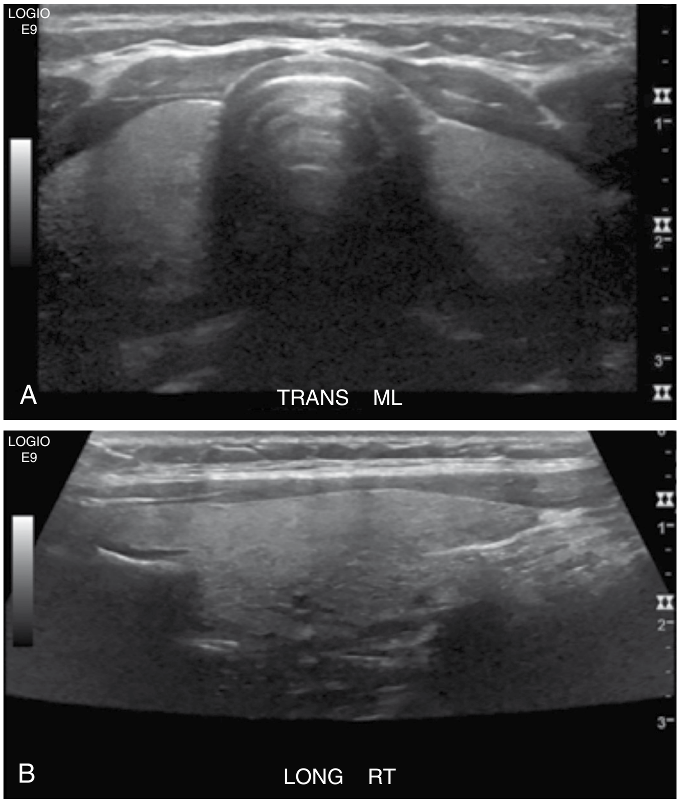

FIGURE 73.8 Normal appearance of the thyroid gland on neck ultrasound. Note the homogeneous echogenicity with uniform echotexture of the gland. (A) Transverse midline view with the two lobes on either side of the trachea. (B) Longitudinal view of the right thyroid lobe. *ML,* Midline; *RT,* right.

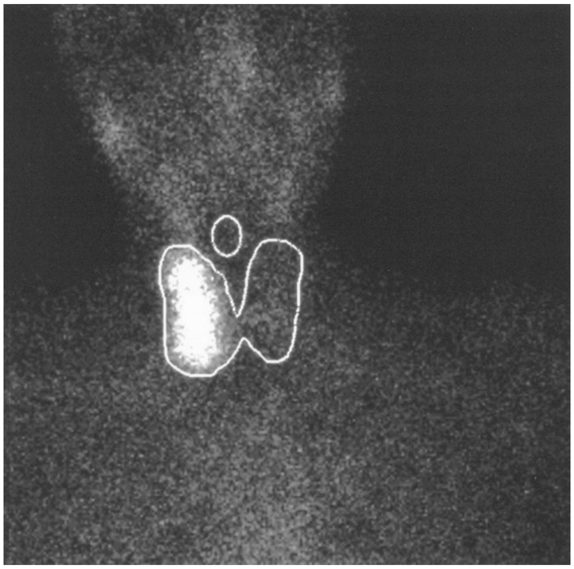

FIGURE 73.9 ^{131}I scan demonstrating an area of increased uptake in the right lobe of a 32-year-old patient with increased thyroid function test values and a palpable nodule. This scan is consistent with a toxic or hyperfunctioning nodule.

to be benign toxic nodules with extremely low risk of malignancy, whereas "cold" nodules carry a 15% risk of malignancy.

Improvements in ultrasonography and cross-sectional imaging over the past few decades have rendered thyroid scintigraphy obsolete in all but a few scenarios. A thyroid uptake scan is useful for the differential diagnosis of hyperthyroidism by determining whether increased radiotracer uptake occurs diffusely throughout the gland as in the case of Graves disease or in more discrete "hot" nodules in cases of solitary toxic adenoma or toxic multinodular goiter (TMG). In addition, radiolabeled iodine scans (usually referred to as *RAI scans*) are commonly performed to assess for, and treat, persistent/recurrent or metastatic disease in the setting of DTC (see later).

Cross-Sectional Imaging

Computed tomography (CT) or magnetic resonance imaging (MRI) scans can be useful adjuncts to ultrasound for specific indications because they can provide precise cross-sectional anatomic assessment of the thyroid gland relative to the other structures in the neck, including the larynx and trachea, esophagus, muscles, and major vascular structures. These modalities are helpful particularly for two scenarios: substernal (intrathoracic) goiter and advanced thyroid cancer (Fig. 73.10). CT and MRI have improved ability over ultrasound in visualizing the infraclavicular

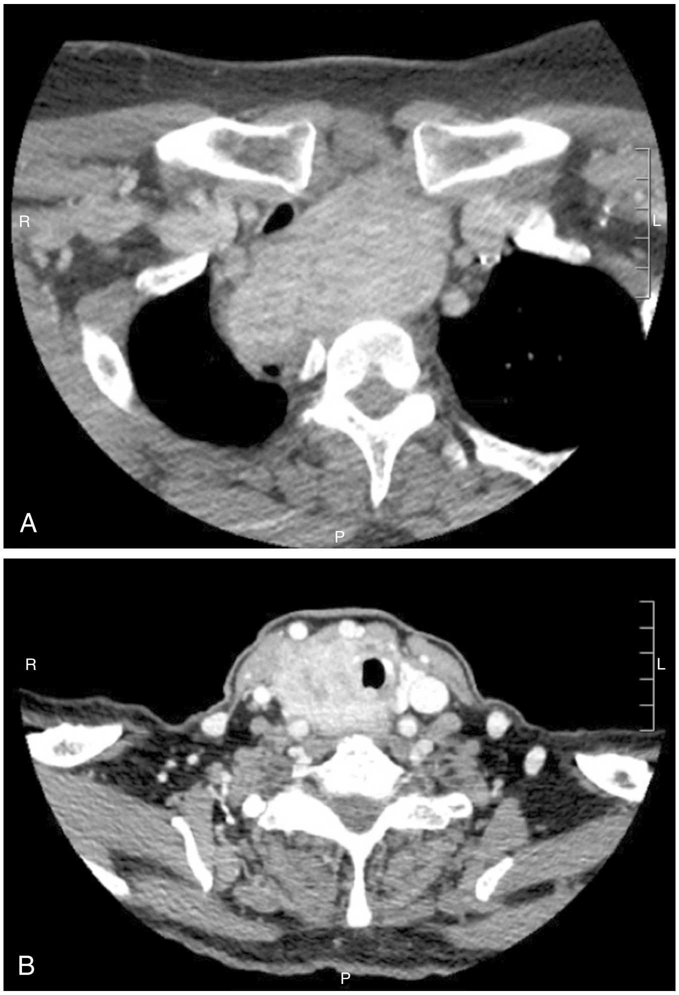

FIGURE 73.10 Computed tomography (CT) scans provide useful anatomic information about the thyroid in selected scenarios. (A) Contrast-enhanced CT scan demonstrating a left-sided substernal goiter extending into the posterior mediastinum and crossing over to the right side with tracheal compression and deviation of both the trachea and esophagus. (B) Contrast-enhanced CT scan of a bulky, locally advanced follicular thyroid cancer originating in the right lobe with invasion into the lateral tracheal wall and esophagus and obliteration of the right internal jugular vein.

mediastinum. In addition, cross-sectional imaging more readily detects vascular anomalies such as the lusoria artery that can alert the surgeon to complex anatomic situations (e.g., presence of non-RLN) and assist with perioperative planning. Many surgeons prefer CT over MRI because of its greater ease of interpretation as well as its superiority over MRI in the detection of cervical lymph node metastases.

If ordered, cross-sectional thyroid imaging should evaluate not just the neck but a wide craniocaudal dimension from the skull base to the tracheal bifurcation in order to accurately assess the extent of intrathoracic goiter or malignancy. Both CT and MRI can be performed with or without IV contrast, depending on the clinical scenario. For evaluation of substernal goiter, a noncontrast CT or MRI is sufficient. On the other hand, IV contrast is indicated for clinical suspicion of advanced thyroid cancer such as locally advanced tumors or those with multiple and/or bulky lymph node metastases in the preoperative setting. Contrast-enhanced images are best for assessing local invasion into neighboring structures, particularly the aerodigestive tract.

On noncontrast CT scan, the thyroid appears homogeneous and mildly hyperattenuating compared with the surrounding muscles, whereas iodinated contrast administration leads to fairly bright diffuse enhancement. On MRI, the thyroid can be mildly hyperintense on both T1- and T2-weighted images, with bright enhancement on gadolinium contrast administration. Incidental thyroid nodules can be found in up to 9% of neck CT or MRI scans. Iodine is generally cleared within 4 to 8 weeks after iodinated contrast administration, which generally does not cause a clinically significant delay in postoperative RAI administration for DTC.

Positron Emission Tomography

Positron emission tomography (PET, typically coupled with CT or MRI) is most frequently performed with the administration of [^{18}F]-fluorodeoxyglucose (FDG) radiotracer, which is taken up in tissues with elevated metabolism of glucose. The normal thyroid takes up [^{18}F]-FDG to a similar level as surrounding skeletal muscle. The role of [^{18}F]-FDG PET is limited to selected cases of higher-risk thyroid cancers, such as for surveillance and staging for RAI-refractory DTC.

PET is not recommended for the routine evaluation of thyroid disease. However, with greater use of these scans, along with other cross-sectional modalities for cancer surveillance purposes, incidental thyroid nodular disease is being detected by PET scans with increasing frequency. Up to 3% of PET scans identify incidental thyroid nodules. PET-positive nodules are generally associated with an elevated risk of malignancy, particularly compared with thyroid nodules found incidentally on other imaging studies (20% on average),[5] but this fact does not supersede the need for standard evaluation with neck ultrasound and FNA biopsy before consideration of surgical management.

HYPOTHYROIDISM

Hypothyroidism is a disorder characterized by inadequate thyroid hormone production and/or availability in peripheral target tissues. Hypothyroidism is a common disorder in the world, although the specific causes differ depending on geography. The most common cause overall is iodine deficiency, which is primarily encountered in the developing world because of lack of sufficient dietary iodine; the same pathophysiology leads to an elevated risk of developing endemic goiter. In the developed world, the most common causes include autoimmune thyroiditis and iatrogenic hypothyroidism as a result of thyroidectomy or RAI treatment with insufficient thyroid hormone supplementation or replacement.

With respect to the hypothalamic-pituitary-thyroid axis, the overwhelming majority of causes of hypothyroidism are primary—that is, the lack of thyroid hormone production is the result of causes at the level of the thyroid. A small percentage of cases may be the result of inadequate secretion of TSH from the pituitary or thyrotropin-releasing hormone from the hypothalamus, which are referred to as *secondary* or *tertiary hypothyroidism,* respectively.

The symptoms and signs of hypothyroidism can range from mild to no symptoms to the classic presentation of cold intolerance, fatigue, puffiness and weight gain, dry skin, and hair loss. Myxedema represents an extreme of symptomatic hypothyroidism in which patients develop a constellation of severe findings, such as altered mental status or coma, hypothermia, bradycardia, and electrolyte abnormalities, with an increased risk of cardiomegaly, pericardial effusion and ascites, and shock. Myxedema typically occurs as a decompensation of chronic hypothyroidism because of an acute physiologic stressor, such as trauma, infection, or an acute cardiovascular event.

Thyroid function tests, and particularly TSH, are highly sensitive for screening for hypothyroidism. In adults, primary hypothyroidism is generally suspected when serum TSH levels are above 4.12 mIU/L, although normal ranges differ depending on age as well as pregnancy.[6] Further testing typically includes measurement of thyroid hormones, including free T_4 and T_3 levels. Elevated TSH levels with decreased free T_4 and T_3 levels are diagnostic of primary hypothyroidism. Elevated TSH levels with relatively normal levels of thyroid hormones are considered to be subclinical or mild hypothyroidism.

Hypothyroidism is fortunately easily treatable with pharmacologic agents such as levothyroxine (LT_4) or liothyronine (LT_3), which are synthetic versions of T_4 and T_3, respectively. LT_4 is recommended as the first-line therapy in most patients for the treatment of hypothyroidism and is available in oral, intramuscular, and IV forms. The rationale for LT_4 lies in the body's ability to convert the exogenously administered T_4 into T_3 by deiodinases in the peripheral tissues. Other therapeutic strategies include a combination of LT_4 and LT_3, LT_3 alone, and desiccated thyroid extracts; all strategies were developed under the hypothesis that LT_4 administration alone may be insufficient to replicate the normal euthyroid state, whether the result of inadequate in vivo conversion to T_3 or the absence of some other heretofore undescribed molecule(s). None of these options is recommended currently as routine first-line therapy. Regarding combination LT_4 and LT_3 therapy, multiple randomized controlled trials have failed to demonstrate superiority over LT_4 monotherapy in various outcomes, including achievement of target TSH and thyroid-specific symptoms and thyroid-specific health outcomes. Further research is needed to study the possible benefit of combination therapy in selected patients with low serum T_3 levels or persistent symptoms on monotherapy. Both LT_3 monotherapy and thyroid extract regimens have some preliminary supporting evidence on short-term outcomes and preference, but high-quality, long-term data on safety and equivalent efficacy are lacking.

Autoimmune Thyroiditis

Autoimmune thyroiditis is the most frequent cause of hypothyroidism in iodine-replete populations. The most common type is chronic lymphocytic thyroiditis, otherwise known as *Hashimoto thyroiditis.* This disorder is found predominantly in females at up to a 10:1 female-to-male incidence ratio. In addition, there is a strong hereditary component, with first-degree relatives of patients with Hashimoto thyroiditis having a ninefold risk of also developing the disease. The etiology of Hashimoto thyroiditis is the presence of circulating autoantibodies to thyroid antigens, resulting in a chronic autoimmune destructive process involving the formation of immune complexes and complement in the basement membrane of follicular cells. This leads to the infiltration of lymphocytes into the thyroid follicles and eventually results in fibrosis, which decreases the effective number of follicles able to produce thyroid hormones.

The biochemical workup for Hashimoto thyroiditis includes measurement of thyroid function tests as well as circulating thyroid autoantibodies, including TPOAb and TgAb (see earlier), which are present in 95% and 60% of patients, respectively. Euthyroid and subclinically hypothyroid patients with elevated autoantibody titers are at greater risk of progressing to overt hypothyroidism. In addition, thyroid autoantibody measurement is recommended in patients at higher risk of developing hypothyroidism, including those with other autoimmune diseases or taking drugs such as lithium or amiodarone.[6]

There is typically no role for imaging studies in the workup and diagnosis of Hashimoto thyroiditis. However, patients with Hashimoto thyroiditis will frequently have symptoms of neck discomfort, pain, and globus sensation, necessitating neck ultrasound for diagnostic workup. Sonographic characteristics of Hashimoto thyroiditis include coarse, heterogeneous, and hypoechoic parenchymal echotexture with increased vascularity, often with the presence of fine echogenic septae producing a pseudonodular appearance that can sometimes be confused with discrete thyroid nodules (Fig. 73.11). The size of the thyroid may range from diffusely or focally enlarged to small and atrophic, and there may be mildly enlarged and more numerous perithyroidal lymph nodes from the autoimmune inflammatory process. Hashimoto thyroiditis has been associated with an increased risk of papillary thyroid cancer (PTC), but possibly with a slight improvement in prognosis based on several single-institution surgical series. As a result, any suspicious thyroid nodules or lymph nodes in the setting of Hashimoto thyroiditis should be worked up with FNA biopsy.

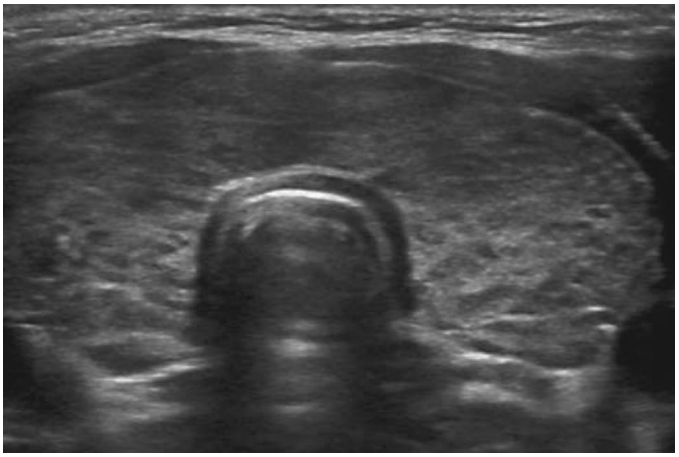

FIGURE 73.11 Sonographic features of Hashimoto thyroiditis. In this image, the thyroid gland is enlarged, predominantly hyperechoic, and diffusely heterogeneous, with irregular echotexture and poorly defined hyperechoic regions separated by fibrous strands. (From Andrioli M, Valcavi R. Sonography of normal and abnormal thyroid and parathyroid glands. *Front Horm Res.* 2016;45:1-15.)

Cytologic features of Hashimoto thyroiditis include a moderately cellular specimen with aggregates of follicular cells with oncocytic changes, minimal colloid, and infiltration of mature lymphocytes. Giant cells, plasma cells, macrophages, histiocytes, and eosinophils also may be seen. Primary thyroid lymphoma, a rare thyroid malignancy with an annual incidence of 2 per 1 million, is associated with Hashimoto thyroiditis and can often be difficult to distinguish based on cytology because of similarities around having large numbers of lymphoid cells and lymphoid follicles with decreased colloid.

The second most common type of autoimmune thyroiditis is postpartum thyroiditis, which can occur in up to 10% of females within the first 2 to 12 months of the postpartum period. The pathogenesis of postpartum thyroiditis appears to have similarities and parallels to that of Hashimoto thyroiditis in that (1) hypothyroidism may be preceded by a short thyrotoxic state, (2) it is often associated with the presence of circulating TPOAb, and (3) postpartum thyroiditis is associated with a tenfold risk of ultimately developing Hashimoto thyroiditis. Postpartum thyroiditis is typically short-lived, with resolution in 2 to 4 months. A short course of exogenous thyroid hormone supplementation/replacement may be necessary.

Subacute Thyroiditis

Subacute thyroiditis, also known as *de Quervain disease* or *subacute granulomatous thyroiditis,* is a relatively uncommon disease found primarily in the developed world. It has a female preponderance, with a 2:1 female-to-male ratio, and typically occurs in the fourth decade of life. The pathogenesis remains poorly understood, but the disease often occurs after a viral prodrome, such as an upper respiratory infection. The hallmark of the clinical presentation for de Quervain thyroiditis is pain and swelling in the thyroid region, along with low-grade fevers, dysphagia, and severe fatigue. Biochemical findings may include an elevated erythrocyte sedimentation rate, which is diagnostic. As with autoimmune thyroiditis, de Quervain thyroiditis can be associated with transient hyperthyroidism followed by hypothyroidism. Cytopathologic characteristics from FNA biopsy include the presence of multinucleated giant cell granulomas. Histopathology shows evidence of granulomatous changes in the thyroid follicles. The follicles are enlarged, with infiltration by mononuclear cells, neutrophils, and lymphocytes.

The time course of de Quervain thyroiditis is typically 2 to 5 months, and most patients return to a euthyroid state spontaneously. Because of its self-limited course, no specific treatments are indicated except for symptomatic relief of pain and/or temporary treatment of clinical hypothyroidism. The pain associated with de Quervain thyroiditis can be treated with nonsteroidal antiinflammatory drugs; more severe cases can be treated with a course of corticosteroids. Surgery is not typically indicated for treatment of de Quervain thyroiditis, and reassurance and emotional counseling are often necessary, particularly during the painful phase of the disease.

Riedel Thyroiditis

Riedel thyroiditis, also known as *Riedel struma* or *chronic fibrous thyroiditis,* is an extremely rare and poorly understood inflammatory process causing diffuse destruction and fibrosis of the thyroid. The primary theories for the etiology of this disease are that it is either an autoimmune process or a specific fibrotic disorder related to multifocal fibrosclerosis. The most relevant finding in Riedel thyroiditis is the presence of an extremely firm and constricting gland that can be very uncomfortable for patients. The fibrotic process often extends into surrounding structures, including the aerodigestive tract and RLN, which may cause clinically significant airway obstruction, dysphagia, and dysphonia.

Patients with Riedel thyroiditis have the biochemical markers of hypothyroidism. Imaging is necessary to rule out other causes of the dramatic local symptoms. Ultrasound characteristics often demonstrate a diffusely hypoechoic gland with ill-defined borders. FNA cytology reveals dense fibrotic changes but cannot be reliably distinguished from fibrotic changes often associated with anaplastic thyroid cancer (ATC).

Medical treatment for the inflammatory component of Riedel thyroiditis traditionally consists of corticosteroids and tamoxifen. Other agents such as mycophenolate and rituximab also have been used. Thyroid hormone supplementation/replacement is used to treat the associated hypothyroidism. Surgical resection is often indicated to rule out malignancy such as ATC or primary thyroid lymphoma or to treat aerodigestive tract obstruction. Surgery is usually extremely challenging because of the firmness of the gland and obliteration of normal planes and landmarks. Partial resection of only the affected components is recommended, with simple wedge resection of the isthmus being the most common surgical therapy for relief of tracheal compression. There is no evidence to suggest that Riedel thyroiditis is associated with an increased risk of thyroid malignancy.

Acute Suppurative Thyroiditis

Acute suppurative thyroiditis is rare and defined as an acute pyogenic infection of the thyroid gland. The most common underlying cause is infection of a congenital pyriform sinus fistula that tracks and communicates with the thyroid. The clinical presentation of acute thyroiditis is that of a bacterial infection: fever, severe unilateral pain and swelling at the thyroid gland (typically left-sided), and cervical lymphadenopathy. The most common organisms include the *Staphylococcus* and *Streptococcus* species, but other aerobic or anaerobic species also may be involved. The thyroiditis also can lead to thyroid abscess formation; rarely, it can lead to even more serious sequelae, including retropharyngeal abscess, tracheal obstruction, mediastinitis, and jugular venous thrombosis.

Thyroid function tests are rarely useful in the diagnosis of acute suppurative thyroiditis; rather, other biochemical findings of acute systemic illness and sepsis are more useful, such as a complete blood count marked by a leukocytosis with a left shift. Ultrasound with FNA biopsy can be useful for bacterial culture and speciation of any abscess fluid. Treatment consists of targeted antibiotics as well as percutaneous drainage of any identified abscess. Acute thyroiditis does not generally lead to long-term hypothyroidism requiring thyroid hormone supplementation.

Iatrogenic Hypothyroidism

Aside from postthyroidectomy hypothyroidism caused by the absence of sufficient thyroid parenchyma, pharmacotherapy is the primary cause of iatrogenic hypothyroidism. The number and variety of medications and therapies that are associated with hypothyroidism are extensive (Box 73.1). The most common medications associated with hypothyroidism include RAI (^{131}I), antithyroid thionamides (such as methimazole and propylthiouracil [PTU]), amiodarone, lithium, immune modulators, and kinase inhibitors.

The etiology of drug-induced hypothyroidism depends on the specific agent. In the case of RAI therapy, the often-expected hypothyroidism is caused by direct destruction of the thyroid follicular cells by the delivered radioactive agent. Thionamides such as methimazole and PTU directly inhibit T_4 and T_3 synthesis (as well as block peripheral conversion of T_4 to T_3 in the case of PTU). The antiarrhythmic agent amiodarone can lead to both hypothyroidism and hyperthyroidism caused by a number of mechanisms, including inability to escape from the Wolff-Chaikoff effect from the drug's high iodine content, inhibition of deiodinase activity, inhibition of thyroid hormone entry into the periphery, and direct cytotoxic thyroiditis (see later). Lithium may act by directly inhibiting the cyclic adenosine monophosphate (cAMP)–dependent pathway, leading to thyroid hormone formation in the thyroid follicle. Tyrosine kinase inhibitors (TKIs) such as sunitinib and vandetanib cause hypothyroidism in different ways, including direct destructive autoimmune thyroiditis, reduction in vascular endothelial growth factor (VEGF)–related thyroid vasculature, and reduction of thyroid iodine uptake.

BOX 73.1 Medications That May Cause Iatrogenic Hypothyroidism

Inhibition of Thyroid Hormone Synthesis or Secretion

- Aminoglutethimide
- Lithium
- Perchlorate
- Thalidomide
- Thionamides (methimazole, propylthiouracil)
- Iodine-containing medications
  - Amiodarone
  - Iodinated IV contrast
  - Guaifenesin
  - Kelp
  - Potassium iodide
  - Topical antiseptics

Immune Dysregulation

- Interferon alfa
- Interleukin-2
- Alemtuzumab
- Ipilimumab
- Nivolumab
- Pembrolizumab

TSH Suppression

- Dopamine

Destructive Thyroiditis

- Sunitinib

Increased Type 3 Deiodinase Activity

- Sorafenib

Increased T_4 Clearance and TSH Suppression

- Bexarotene

T_4, Tetraiodothyronine or thyroxine; *TSH*, thyroid-stimulating hormone.

Treatment of drug-related hypothyroidism usually consists of removal of the offending agent if possible as well as thyroid hormone supplementation/replacement as necessary.

HYPERTHYROIDISM

Hyperthyroidism is defined as a clinical state of elevated thyroid hormone action in tissues, usually because of inappropriately high constitutive secretion of thyroid hormone from the thyroid. The degree of severity of hyperthyroidism is typically divided into two groups: overt (suppressed TSH levels with concomitant elevations in free T_4 or T_3) and subclinical (suppressed TSH with normal free T_4 and T_3). Both overt and subclinical hyperthyroidism can lead to clinically significant symptoms or signs, although subclinical disease is more likely to be milder in presentation.

The clinical symptoms and signs of hyperthyroidism are broad, reflecting the fact that thyroid hormone exerts an effect on nearly every organ system. Overt hyperthyroidism can cause a litany of effects, including tremor, heat intolerance, tachycardia and atrial fibrillation, increased gastrointestinal motility, muscle weakness, anxiety, and embolic events. Uncontrolled hyperthyroidism can rarely cause severe cardiovascular complications, including cardiomyopathy and congestive heart failure that can even progress to cardiovascular collapse and death. Subclinical hyperthyroidism typically has milder manifestations along this same disease symptomatology.

The prevalence of hyperthyroidism worldwide is approximately 2.5%.[7] The most common causes of hyperthyroidism—Graves disease, TMG, and solitary toxic adenoma—are all those in which thyroidectomy plays an important, if not primary, role in management. These three disease states are discussed in further detail next. Other causes of hyperthyroidism are listed in Box 73.2, and amiodarone-induced thyrotoxicosis (AIT) is also discussed.

Graves Disease

Graves disease, named after Dr. Robert J. Graves who first described the condition in the 1830s, is an autoimmune disease characterized by the constitutive activation of the TSH receptor by TRAb, which results in increased synthesis and secretion of thyroid hormone. Graves disease is the most common cause of hyperthyroidism in the United States, with an estimated incidence of 30 cases per 100,000 persons per year. The disease has a female predominance, with an 8:1 female-to-male ratio, and typically presents during younger adult life, with a typical patient age range of between 20 and 40 years.

Because of its autoimmune etiology, Graves disease can have other manifestations in addition to the classic symptoms and signs of hyperthyroidism. The most common is Graves orbitopathy, which occurs in up to 25% to 30% of patients. In this process, autoimmune reactions at the orbital and periorbital soft tissues lead to proptosis, eyelid retraction, chemosis, periorbital edema, and diminished ocular muscle motility (Fig. 73.12); if left untreated, the orbitopathy can lead to vision loss from corneal lesions or optic nerve compression. Skin manifestations also can occur, including pretibial myxedema and acropachy (edema at the digits). Other autoimmune conditions that have been associated with Graves disease include Hashimoto thyroiditis, lupus, rheumatoid arthritis, pernicious anemia, and Addison disease, among others.

BOX 73.2 Causes of Hyperthyroidism

Associated With Normal/Elevated RAI Uptake

Graves disease
Toxic multinodular goiter
Toxic adenoma
Trophoblastic disease
TSH-producing pituitary adenoma
Thyroid hormone resistance

Associated With No/Minimal RAI Uptake

Painless thyroiditis
Amiodarone-induced thyroiditis
Subacute thyroiditis
Iatrogenic thyrotoxicosis
Struma ovarii
Acute thyroiditis
Follicular thyroid cancer metastases
Palpation thyroiditis

RAI, Radioactive iodine; *TSH,* thyroid-stimulating hormone.

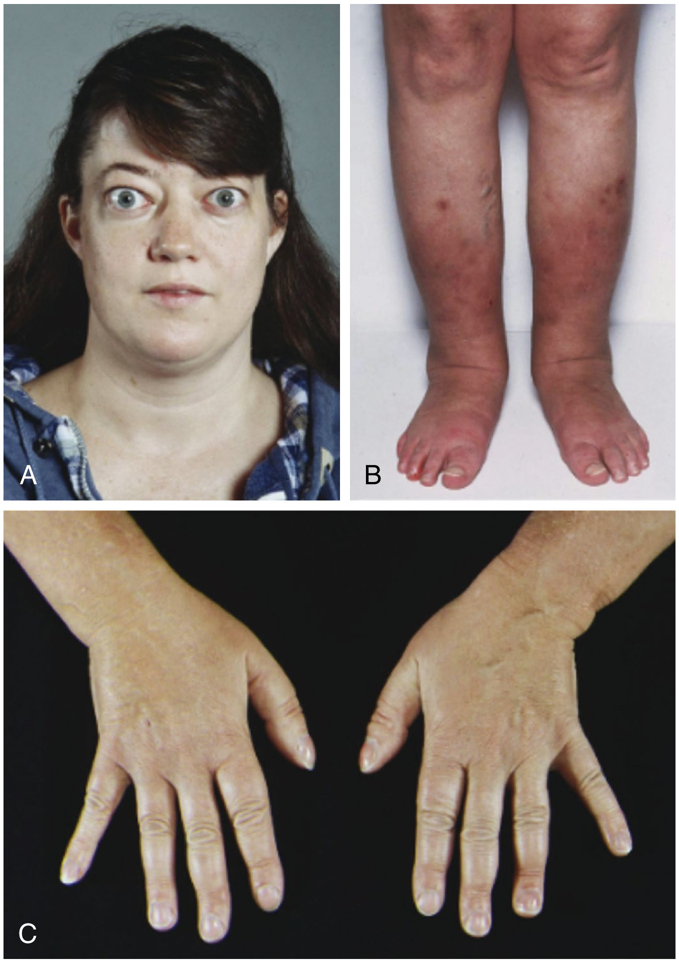

FIGURE 73.12 Extrathyroidal manifestations of Graves disease. (A) Orbitopathy. (B) Dermopathy (pretibial myxedema). (C) Acropachy. (From Al-Shoumer KAS, Gharib H. Hyperthyroidism: toxic nodular goiter and Graves' disease. In: Randolph GW, ed. *Surgery of the Thyroid and Parathyroid Glands 2.* Philadelphia: Elsevier Saunders; 2013:53.)

The biochemical workup for Graves disease typically includes thyroid function tests, including TSH, free T_4, and T_3 as well as measurement for TRAb (typically with TSI but also with TSH receptor-binding inhibitory immunoglobulin in selected scenarios). The presence of TRAb is diagnostic for Graves disease. Imaging may consist of neck ultrasound and/or nuclear medicine thyroid uptake scan, depending on the indications. Sonographic features may include a diffusely hypervascular gland, often with heterogeneous echogenicity; thyroid nodular disease may also be identified. Nuclear scintigraphy using either ^{99m}technetium pertechnetate or ^{123}I may help differentiate TSI-negative Graves disease from toxic nodular disease based on diffuse versus nodular uptake pattern. Cross-sectional imaging of the head may be useful for the evaluation of orbitopathy.

The three management options for Graves hyperthyroidism include antithyroid medications, RAI ablation, and thyroidectomy. In the United States, RAI is the most employed treatment option, although antithyroid medication is being used more frequently as a first option; nearly one-third of patients may be able to achieve long-term remission with medication alone. In truth, each of the three treatment options comes with its own unique set of advantages and disadvantages as well as indications and contraindications, which must be tailored according to individual patient values and preferences. The 2016 ATA guidelines on the management of hyperthyroidism provide a helpful evidence-based summary of the clinical scenarios that would most favor a particular option for treatment (Table 73.1).[8]

In general, thyroidectomy is the preferred modality in the following situations: presence of severe eye disease, failure or contraindications to other treatment options, need or desire for rapid reversal of hyperthyroidism, presence of concomitant suspicious thyroid nodules, large goiters with locally compressive symptoms, and pregnancy or postpartum/breastfeeding states. Although thyroidectomy is a first-line treatment option, in practice, it is often relegated to a secondary role because of perceived risks associated with general anesthesia and surgery. Although RAI ablation is often billed as extremely low-risk or no-risk, emerging evidence suggests a higher rate of secondary malignancy than previously reported.[9]

For patients choosing surgical management, the recommended extent of surgery is a total or near-total thyroidectomy, which is associated with a nearly 0% risk of recurrent hyperthyroidism. In contrast, subtotal thyroidectomy is associated with a 5% to 10% risk of recurrence from the presence of residual thyroid tissue. Although the risk of thyroidectomy-specific complications (including permanent hypoparathyroidism, RLN injury, and neck hematoma) is higher in Graves disease than for other indications, the absolute risks remain low, particularly in the hands of higher-volume surgeons, and there are no differences between total/near-total and subtotal thyroidectomy groups. The rate of permanent RLN injury is 0% to 2%, permanent hypoparathyroidism is 0.6% to 6%, and neck hematoma is 0.3% to 0.7% for total thyroidectomy performed in the setting of Graves disease.[10] The risk of complications from remedial thyroidectomy is up to tenfold higher than initial thyroidectomy, which further underscores why subtotal thyroidectomy (with its risk of recurrent disease) is no longer favored.

Patients ideally should be rendered euthyroid before thyroidectomy with antithyroid medications, but recent studies suggest that the risk of thyroid storm during thyroidectomy in actively thyrotoxic patients is minimal.[11] The most commonly used antithyroid drug is methimazole because PTU was found to be more often associated with liver failure resulting in the need for transplantation.[12] β-Blockers may be added for patients who remain hyperthyroid and/or tachycardic. High-concentration potassium iodide solutions, including Lugol solution or super saturated potassium iodide (SSKI), can be given for 7 to 10 days before surgery; they are thought to be beneficial for decreasing thyroid blood flow and vascularity of the gland and help to rapidly achieve a euthyroid state via the Wolff-Chaikoff effect. Their use

TABLE 73.1 Clinical Situations That Favor a Particular Modality as Treatment for Graves Hyperthyroidism

CLINICAL SITUATIONS	RADIOACTIVE IODINE	ANTITHYROID DRUG	SURGERY
Pregnancy	×	√√/!	√/!
Comorbidities with increased surgical risk and/or limited life expectancy	√√	√	×
Inactive Graves ophthalmopathy	√	√	√
Active Graves ophthalmopathy	!	√√	√√

One or more large thyroid nodules	-	√	√√
Coexisting primary hyperparathyroidism requiring surgery	-	-	√√

√√ = Preferred therapy; √ = acceptable therapy; ! = cautious use; - = not first-line therapy but may be acceptable depending on the clinical circumstances; × = contraindication.

From Ross DS, Burch HB, Cooper DS, et al. 2016 American Thyroid Association guidelines for diagnosis and management of hyperthyroidism and other causes of thyrotoxicosis. *Thyroid*. 2016;26:1343-1421.

may not be helpful or needed in selected situations. All other associated medical and surgical comorbidities should be optimized, including repurposing of cholestyramine or lithium to decrease circulating free thyroid hormone levels.[13] Preoperative optimization of calcium and vitamin D status, including preoperative supplementation with calcitriol, has been shown to decrease the postoperative risk of transient hypocalcemia.

Thyroid storm is a rare state of life-threatening physiologic decompensation in patients with severe, uncontrolled hyperthyroidism, which often occurs after an inciting stressor event. The symptoms can be dramatic and severe, including fever; cardiac effects including hypertension, tachycardia, arrhythmia, and congestive heart failure; mental status changes including agitation, stupor, and coma; and hepatic failure. Treatment is multimodal and consists of β-blockade, antithyroid medications, potassium iodide, corticosteroids, mechanical cooling therapies, and intensive supportive care. Plasmapheresis also has been reported to rapidly decrease circulating thyroid hormone levels and should be considered as another option in the armamentarium in severe cases, although its use is limited by cost and availability.[14]

Toxic Multinodular Goiter

TMG is an enlarged nodular thyroid containing one or more autonomously functioning nodules leading to a state of hyperthyroidism. This condition is also known as *Plummer disease,* so named after Henry Plummer of the Mayo Clinic in 1913. TMG is the second most common cause of hyperthyroidism in the United States after Graves disease. Among the elderly and those who live in iodine-deficient regions, TMG is the most common cause of hyperthyroidism. TMG has a female predominance, with an approximately 5:1 female-to-male ratio, and typically affects adults above the age of 50 years.

Autonomously functioning nodules in TMG often result from mutations in the TSH receptor gene leading to constitutive synthesis and secretion of thyroid hormones. These “warm” or “hot” nodules are rarely malignant and typically do not require biopsy. However, they can coexist with other nonfunctioning nodules in the same gland, which should be evaluated independently (see “Thyroid Nodule” section later).

The workup of TMG consists of both biochemical and radiographic testing. As with Graves disease, thyroid function tests are mandatory in order to diagnose hyperthyroidism. In addition, a survey of thyroid antibodies (including TRAb) is necessary to identify coexisting autoimmune thyroiditis and rule out Graves disease. Nuclear scintigraphy is a first-line imaging study and, in the case of TMG, can identify the location and distribution of autonomously functioning nodules and/or regions. In addition, ultrasound is highly recommended as a correlative study to assess overall thyroid size and characterize any nonfunctioning nodules that may require biopsy.

The three management options for TMG—antithyroid medication, RAI, and thyroidectomy—are the same as those for Graves disease, but with some differences. First, antithyroid medication is generally not advocated as a long-term management strategy except for patients in whom the other two options are absolutely contraindicated, such as in some elderly or otherwise ill or frail patients with limited life expectancy. Because this disease state is not autoimmune in nature, autonomous nodules do not undergo remission with medical therapy. Second, RAI with ^{131}I is the most common definitive treatment for TMG in the United States; however, the dose of radiation is typically higher (and, by extension, the risk of treatment failure and need for retreatment) than in Graves disease because of lower uptake of iodine in TMG. Third, both RAI and surgery should be preceded by optimal preoperative treatment of the hyperthyroid state, which typically includes methimazole with or without β-blockade. SSKI and Lugol solutions are not indicated for TMG as they are for Graves disease because the high iodine concentration may not achieve a temporary euthyroid state from the Wolff-Chaikoff effect. They induce hyperthyroidism from the Jod-Basedow phenomenon.

Near-total or total thyroidectomy is the generally recommended surgical treatment of TMG. As in the case of Graves disease, complete extirpation can be performed with a similarly low rate of complications as subtotal thyroidectomy while at the same time virtually eliminating the risk of disease recurrence.

Solitary Toxic Adenoma

A toxic adenoma is a single autonomously functioning nodule existing within an otherwise normal or nontoxic nodular thyroid gland. The main theory around its pathogenesis focuses on constitutively activating mutations in the TSH receptor gene, although the prevalence of these mutations is not universal and varies widely by geography. Toxic adenoma affects females at a median age of 50 to 60 years, with a mild female predominance. Toxic adenoma shares many, if not most, of the diagnostic approach and workup with TMG; in fact, the ATA guidelines on the management of hyperthyroidism combine the two groups together in their treatment recommendations.

The treatment philosophy for toxic adenoma generally follows the same principles as those for TMG—namely, that antithyroid medications are not effective for long-term remission, and either RAI or thyroidectomy is the preferred method for definitive treatment. Thyroidectomy is typically limited to unilateral lobectomy addressing the side of the toxic adenoma; this strategy is associated with a near-universal cure for the hyperthyroidism. Near-total or total thyroidectomy is indicated only in the presence of other factors, such as bilateral nodules with suspicion for cancer or a large and/or symptomatic goiter. Thermal ablation techniques, discussed in further detail later in this chapter, have shown variable resolution of hyperthyroidism for toxic adenomas compared with surgery or RAI. Therefore, RFA is not recommended as first-line treatment for large toxic adenomas, but it can be considered in young patients with small toxic adenomas. Small nodules ($<$12 mL in volume) with volume reduction exceeding 80% are more likely to experience resolution of hyperthyroidism.[15]

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an antiarrhythmic medication used frequently for atrial or ventricular tachyarrhythmias. Molecularly, amiodarone is an iodine-rich compound with structural similarities to T_4 that contains 37% iodine content by molecular weight; a normal dosing schedule can deliver over 100 times the daily dietary iodine requirement. AIT occurs in up to 6% of patients taking this medication.

Two distinct mechanisms are proposed in the development of AIT. Type 1 AIT is caused by the Jod-Basedow phenomenon, in which the high iodine load potentiates excess thyroid hormone synthesis and release. Type 1 AIT is more common in patients with preexisting hyperthyroid disease. Type 2 AIT usually occurs in patients with no preexisting thyroid disease and is caused by a destructive thyroiditis from direct drug toxicity on follicular cells, leading to release of preformed thyroid hormone. Mixed forms of AIT also can occur.

Medical treatment of AIT typically consists of methimazole, with corticosteroids added to address the thyroiditis in type 2 AIT. The decision to halt amiodarone treatment must be determined carefully on an individual basis in consultation with the treating cardiologist in order to ensure continuity of adequate antiarrhythmic therapy in these often high-risk patients. Total thyroidectomy is recommended for patients who are unresponsive to aggressive medical therapy. Although thyroidectomy is associated with more risks for AIT compared with most other indications (with perioperative mortality of 9%–10%), delay in surgery carries an even higher risk of mortality.[16]

NONTOXIC GOITER

A nontoxic goiter is defined as any benign, noninflammatory enlargement of the thyroid gland that is not associated with hyperthyroidism. The causes of nontoxic goiter can be broadly divided into diffuse and nodular enlargement, which roughly lead to the respective entities of endemic/diffuse and sporadic multinodular goiter, each with their own pathogenesis, risk factors, and management strategies.

Endemic (Diffuse) Goiter

Strictly defined, endemic goiter occurs in more than 10% of a given population; however, the only known cause of endemic goiter is dietary iodine deficiency, which predisposes people predominantly to diffuse goiter from persistent TSH stimulation, leading to diffuse follicular epithelial hyperplasia. In effect, the terms *endemic goiter* and *diffuse goiter* have functionally become synonymous.

It is estimated that more than 2 billion people worldwide are exposed to iodine-deficient diets.[17] In iodine-deficient populations, a palpable goiter can be detected in up to 40% to 90% of individuals, and hypothyroidism can be found in up to 50%. The risk of goiter and hypothyroidism increases proportionally with the severity of iodine deficiency. There is a female predominance in the prevalence of endemic goiter (approximately two to three times higher than in males), and its incidence increases by age group because of its environmental etiology.

The morbidity and mortality from endemic goiter are a result of its association with chronic untreated hypothyroidism and cretinism as much as—if not more than—the local effects on the neck because of its size. Instituting proper iodine supplementation in iodine-deficient populations has been shown to be an effective strategy for decreasing the incidence of these diseases.

Nontoxic Multinodular Goiter

Sporadic multinodular goiter is the most common cause of nontoxic goiter in the United States and other developed nations with iodine-rich diets, with an incidence of approximately 5%. Although there is a known stepwise pathophysiologic process in which iodine deficiency can first cause diffuse follicular hyperplasia and subsequently stimulate nodule formation, the causes of the majority of sporadic multinodular goiter remain unknown. The incidence of multinodular goiter increases with age, probably paralleling the age-related incidence of thyroid nodules in general.

Substernal Goiter

Substernal (or retrosternal) goiter is defined broadly as a goiter with a significant proportion of the gland extending inferiorly through the thoracic inlet and into the mediastinum. The incidence of substernal goiter is estimated at 0.02% in the general population, with 60% occurring among patients who are over the age of 60 years.[18] There are a number of subtypes of substernal goiter. The most common subtype extends into the anterior mediastinum. The second subtype extends posteriorly to the great vessels, trachea, and/or RLN, sometimes crossing over to the contralateral neck. The third and least common subtype is the isolated mediastinal goiter with no connection to the normal cervical orthotopic gland and with unique blood supply from the chest.

Substernal goiters are more likely than cervical goiters to be associated with local compressive symptoms, including shortness of breath/orthopnea and dysphagia. This is because the mediastinal extension of the goiter pushes against and compresses the normal thoracic inlet structures (trachea, esophagus, vascular structures) within a fixed bony space bound by the ribs and vertebrae. Tracheal compression is of particular concern because minor degrees of goiter enlargement and resultant narrowing of tracheal diameter can lead to dramatic reductions in ventilatory flow (Poiseuille's law) in a relatively short period. In contrast, primarily cervical goiters are often capable of dramatic growth without causing significant compressive symptoms because of the expandability of the surrounding cervical soft tissues. Vocal cord paralysis from RLN compression is extremely rare, and the presence of vocal cord dysfunction should raise the concern for malignancy harbored within the goiter.

Workup

The workup of nontoxic goiter consists of thyroid function testing to rule out hyperthyroidism and imaging studies to assess for goiter extent and presence of nodules. The mainstay for thyroid imaging is neck ultrasound, which offers the highest resolution description of thyroid size/volume, presence or absence of significant thyroiditis, and characterization of thyroid nodules. As stated in the ATA guidelines, every nodule at least >1 cm should be evaluated for suspicious sonographic features on an individual basis, and FNA should be performed preferentially based on suspicion for malignancy according to a number of criteria outlined by the ATA and the American College of Radiology (ACR).[19]

Cross-sectional imaging with either CT or MRI is essential for the assessment of—and preoperative planning for—substernal goiter and is indicated for any patient with significant compressive symptoms and/or sonographic evidence of inferior extension past the clavicle (see Fig. 73.10A and Fig. 73.13). Cross-sectional imaging is useful because it provides information about the degree of tracheoesophageal deviation/compression, laterality of dominant substernal lobe, inferior-most extent, anterior versus posterior pattern of extension, presence of cross-over to the contralateral chest, and presence of a separate intrathoracic "rest." Unless there is concern for malignancy, the need for contrast enhancement is typically unnecessary.

Management

The management options for nontoxic goiter generally consist of nonoperative surveillance, TSH suppression with thyroid hormone supplementation, RAI ablation, and thyroidectomy. Small nontoxic goiters generally can be followed expectantly with periodic thyroid function testing and neck imaging. TSH-suppressive therapy with LT_4 is often employed by endocrinologists as a first-line treatment option, particularly for smaller goiters. The results of several large-scale trials are somewhat mixed but do appear to show goiter size reductions in about 30% of patients; however, these results must be balanced against the drawbacks of therapy,

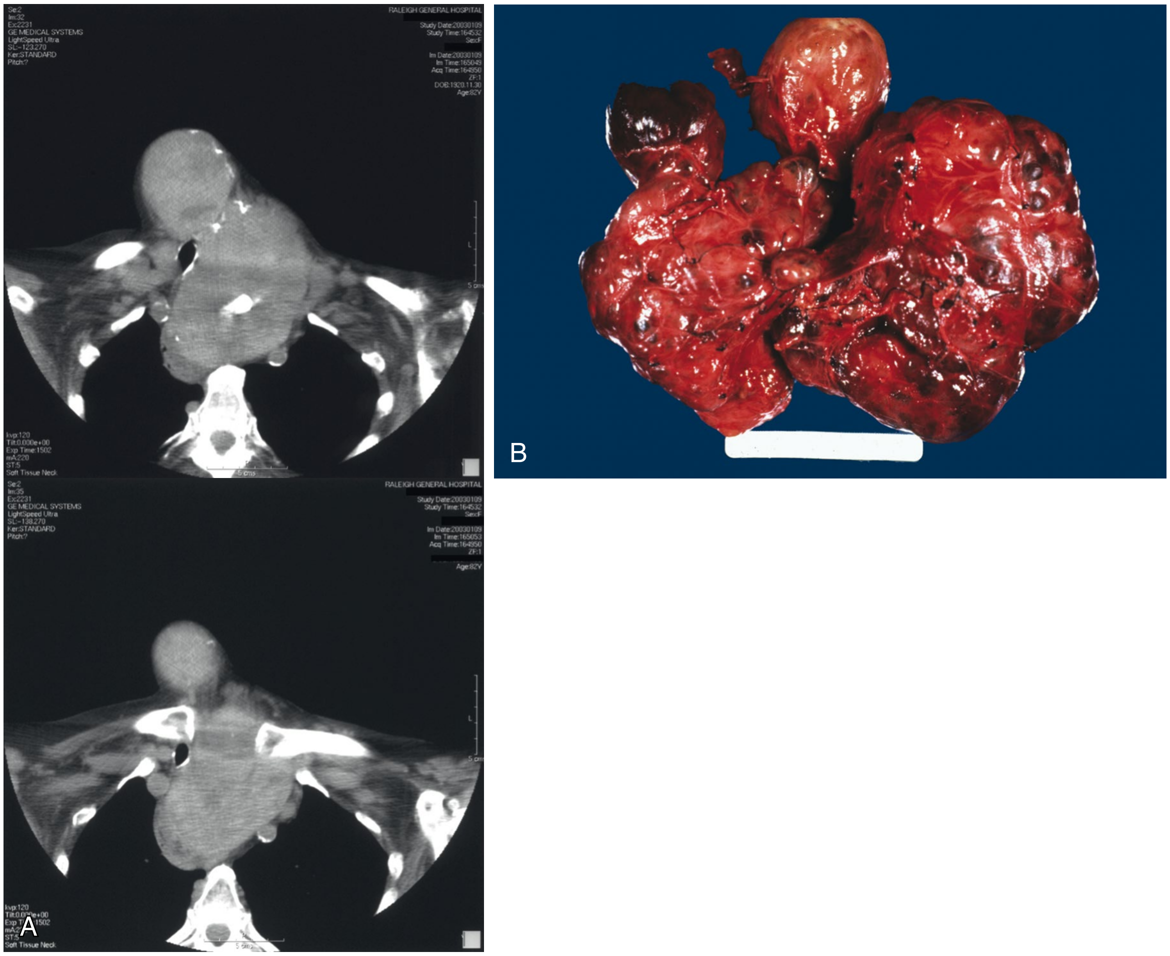

FIGURE 73.13 (A) Computed tomography scan at the level of the thoracic inlet demonstrating a heterogeneous, large thyroid mass that involves both lobes of the thyroid and displaces the trachea. It has extended into the anterior mediastinum. This patient ultimately proved to have a large multinodular goiter. (B) Gross picture of the resected multinodular goiter.

including the need for lifelong suppression and the long-term effects of subclinical hyperthyroidism on the heart and bone.[20] RAI ablation can reduce goiter size by up to 50% over a 1-year period, and it is an increasingly popular treatment option in many developing countries where access to thyroidectomy is limited. However, the effect of RAI is gradual; acute transient thyroiditis can occur, which may exacerbate local symptoms, and it is ineffective for larger goiters.

The absolute indications for thyroidectomy in nontoxic goiter include local compressive symptoms, substernal extension (which often presents with compressive symptoms), presence of nodules suspicious or diagnostic for malignancy in which prolonged ultrasound surveillance would be hampered, and patient preference (assuming that the patient is otherwise an acceptable surgical candidate). The extent of thyroidectomy, specifically unilateral lobectomy versus total thyroidectomy, can be tailored to the individual patient and goiter scenario. Total or near-total thyroidectomy is typically the procedure of choice; subtotal thyroidectomy is associated with an unacceptably high rate of recurrence in the long term (>50% in some studies). However, unilateral lobectomy may suffice in certain scenarios, such as a single-side dominant goiter with a relatively normal contralateral lobe and in patients predicted to have poor adherence to daily thyroid hormone replacement.

Thyroidectomy for substernal goiter presents a unique challenge depending on the amount and pattern of intrathoracic extension, specifically in relation to the probability of requiring partial or complete sternotomy. Most substernal goiters can be resected via standard cervical thyroidectomy incision because the majority of substernal goiters are anterior and extend inferiorly to a point no lower than the superior aspect of the aortic arch on cross-sectional imaging. These goiters can readily be retrieved via cervicotomy with proper neck extension and patient positioning. On the other hand, goiters extending farther inferiorly than the aortic arch, extending posteriorly, and/or crossing the midline from the dominant side are significantly more difficult and may require sternal split and partial or even total median sternotomy. Thoracic surgery assistance is useful, especially for the more difficult substernal goiters requiring sternotomy or other mediastinal access.

THYROID NODULE

A thyroid nodule is a commonly identified discrete lesion within the thyroid gland. Up to 5% of females and 1% of males in iodine-replete areas have palpable thyroid nodules, and with the advent of ever-improving high-resolution ultrasound, the frequency of thyroid nodules has been estimated to be as high as

19% to 68% because of imaging's ability to pick up nonpalpable, incidentally discovered thyroid nodules, or "incidentalomas." Although thyroid nodules are quite common, the majority do not require extensive (or any) workup, and the vast majority do not require surgical intervention. The primary reasons for surgical intervention for thyroid nodules include (1) concern for malignancy, (2) hyperfunction, and (3) locally compressive symptoms.

The management of thyroid nodules (and thyroid cancer) is the subject of much active research and controversy. Multiple organizations have published clinical practice guidelines over the past 25 years. The ATA guidelines were first published in 1996 and updated over the years, most recently in 2006, 2009, and 2015, and arguably remain the most comprehensive, current, and cited among thyroidologists.[19] Much of this section will reflect the evidence and recommendations contained in the most recent iteration of the ATA guidelines.

Clinical Presentation and Workup

The majority of thyroid nodules are benign and asymptomatic, and as mentioned earlier, many are now diagnosed as "incidentalomas." Several clinical findings on history or physical exam raise the suspicion for thyroid cancer. These include patient age <20 years or >70 years, male sex, locally compressive or infiltrative symptoms such as hoarseness or dysphagia, firm and/or immobile nodule, nodules >3 to 4 cm, cervical lymphadenopathy, history of neck irradiation, and history of thyroid cancer in first-degree family members. Although less common, the suspicion for a hyperfunctioning nodule or toxic adenoma is raised when there are symptoms or signs of thyrotoxicosis, including palpitations, atrial fibrillation, anxiety, insomnia, weight loss, heat intolerance, diaphoresis, and increased defecation.

The workup of thyroid nodules typically includes assessment of thyroid function with serum TSH as a screening test as well as neck ultrasound (Fig. 73.14). The finding of a suppressed TSH

level also may trigger further workup of hyperthyroidism as detailed earlier, including thyroid antibody workup and thyroid nuclear medicine scintigraphy. Further workup for malignancy always includes FNA biopsy (see later) and, depending on the concern for locally advanced or metastatic behavior, may include cross-sectional imaging.

The majority of thyroid nodules are benign neoplasms and include colloid nodules, degenerative cysts, nodular hyperplasia, and follicular adenomas. Of note, the 2022 World Health Classification of Thyroid Neoplasms has designated oncocytic adenomas of the thyroid as a distinct classification; the term *Hürthle cell* is now discouraged because it is a historical misnomer.[21] The most common malignant diagnosis is PTC, and in decreasing order of frequency also includes follicular thyroid cancer (FTC), oncocytic carcinoma of the thyroid (OCA), MTC, poorly differentiated thyroid cancer (PDTC), and ATC; other rare malignancies, including primary thyroid lymphoma and metastasis to the thyroid gland, can occur (see the "Thyroid Cancer" section later for more details).

Ultrasound Evaluation of Thyroid Nodules

Neck ultrasound is the most important radiographic study for the evaluation of thyroid nodules. Ultrasound offers the highest-resolution image of the thyroid gland by well characterizing parenchymal and nodular abnormalities; it also provides the most sensitive radiographic assessment of cervical lymphadenopathy. Ultrasound is an essential adjunct for the performance of image-guided FNA biopsy of suspicious nodules and lymph nodes (see later). Other advantages of ultrasound include its portability, absence of the need for ionizing radiation, and overall cost-effectiveness in the initial evaluation and longer-term management of thyroid nodules. Neck ultrasound has been shown in selected patients to be a useful tool for noninvasive assessment of vocal cord function, which is important for informing surgical management.

For patients with hyperthyroidism and thyroid nodules, both nuclear medicine thyroid scintigraphy and ultrasound are recommended in order to determine concordance in the presence of a possible toxic nodule as well as to assess for other "cold" or nonfunctioning nodules.

As neck ultrasound has become more accessible to clinicians and viewed as an extension of the physical examination, it has become more widely used by surgeons and endocrinologists in addition to radiologists. Because the operator dependence of this modality greatly affects the quality of the ultrasound examination, efforts have been made on the national level to provide standardized educational and certification pathways for ultrasound expertise. For surgeons, the American College of Surgeons offers a two-step advanced neck ultrasound training program.

The need for proper education and standardization is especially apparent considering the number and degree of findings that one must assess for and document in every ultrasound. These findings include, at minimum, the following: (1) parenchymal pattern and overall thyroid gland size; (2) presence, size, location, and characteristics of any nodules; and (3) presence/absence, size, location, and characteristics of any suspicious cervical lymph nodes. Survey of the cervical lymph nodes is particularly specialized and important in the evaluation of thyroid nodules. Fig. 73.3 shows the levels of the nodal stations in the neck, with the accepted numeric nomenclature initially created for neck dissection for head and neck cancers. Thorough examination must be performed particularly of the pretracheal and paratracheal nodes of the central neck and mediastinum (levels VI and VII, respectively) as well as the lateral jugular chain nodes (especially levels IIa/IIb, III, IV, and Vb).

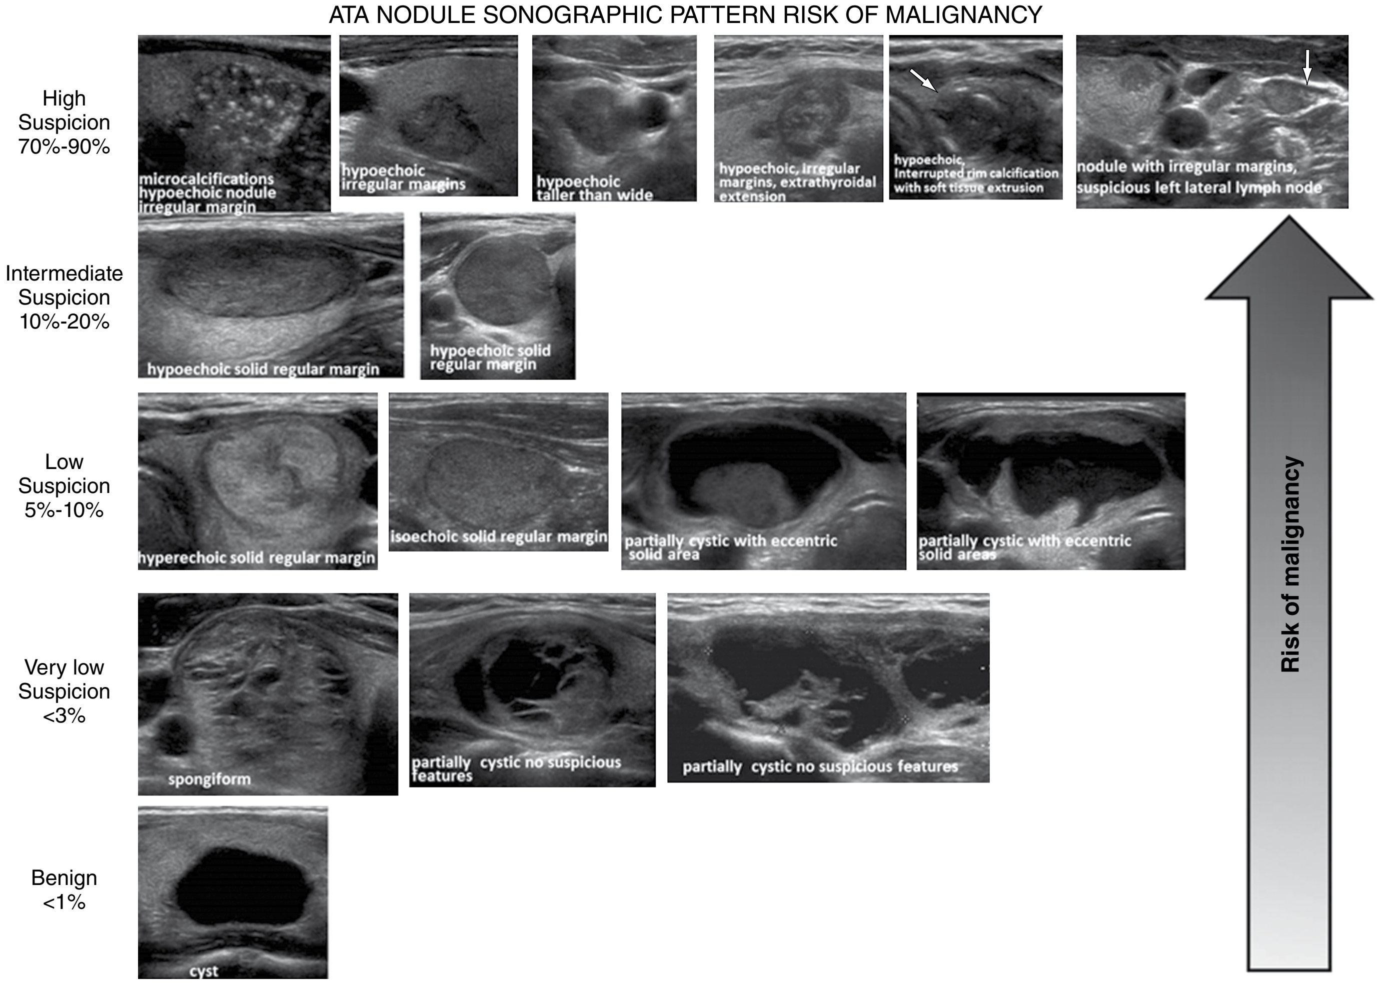
Sonographic Risk Stratification of Thyroid Nodules

The sonographic characteristics in thyroid nodules that appear to confer the highest risk of malignancy—specifically PTC—include (1) the presence of microcalcifications, (2) hypoechogenicity, (3) irregular margins, and (4) a taller-than-wide nodule shape. Size is also thought to be a predictor and is clinically relevant, although whether size is an independent predictor is controversial. Intranodular vascularity has historically been thought to also be predictive of malignancy but is likely more correlated with FTC than PTC. Although each individual ultrasound characteristic is relatively unreliable in isolation for predicting malignancy, the combination provides improved specificity. On the opposite end of the spectrum, features such as spongiform pattern or a purely cystic appearance dramatically decrease the risk of malignancy.

Because the sonographic interpretation for malignancy is based on synthesizing a constellation of features, large-scale efforts have been made to create graduated risk stratification systems, with higher sonographic risk nodules recommended to undergo FNA biopsy at a smaller size threshold. In the 2015 guidelines, the ATA proposed a five-grade sonographic classification system, which is graphically summarized in Fig. 73.15.[19] Only those nodules in the higher-risk categories—called high, intermediate, and low suspicion—have associated definitive recommendations regarding FNA biopsy, whereas the two lower-risk categories—called very low suspicion and benign—can usually be safely observed. Table 73.2 summarizes the sonographic categories, their estimated risks of malignancy, and size-based recommendations for biopsy.

Despite the prominence of the ATA's guidelines for clinical practice, other organizations and societies also have proposed sonographic risk stratification systems for thyroid nodules. Probably the most commonly used alternative is the Thyroid Imaging, Reporting and Data System (TI-RADS), which was originally described in 2005 but formalized by the ACR in 2015. TI-RADS stratifies nodule characteristics into five risk levels, from TR1 (benign) to TR5 (highly suspicious); however, the categorization method differs in that it converts feature patterns into a discrete number of points along five feature dimensions—nodule composition, echogenicity, shape, margin, and echogenic foci—and the total accumulated points determines the ultimate TI-RADS level.[22] The TI-RADS level, in turn, determines size-based recommendations for biopsy or surveillance; the size thresholds also vary somewhat from those of the ATA. Fig. 73.16 shows a summary schematic of the TI-RADS system. Comparative studies to date would suggest that both the ATA and TI-RADS systems perform with high sensitivity and negative predictive value (NPV) and represent a significant improvement in standardization and completeness in ultrasound reporting.[23]

Neither system recommends routine FNA biopsy of nodules less than 1 cm. This strategy accepts the trade-off of not diagnosing all thyroid cancers <1 cm against the current reality of many countries (including the United States) experiencing dramatic increases in overdiagnosis of clinically insignificant papillary thyroid microcarcinomas (PTmCs; see later). However, other factors such as the location of the nodule in the thyroid, presence of lymphadenopathy, genetic or environmental risk factors, patient age, and patient preference may take precedence in influencing whether a subcentimeter thyroid nodule is biopsied.



ATA NODULE SONOGRAPHIC PATTERN RISK OF MALIGNANCY
High Suspicion 70%-90%
microcalcifications hypoechoic nodule irregular margin
hypoechoic irregular margins
hypoechoic taller than wide
hypoechoic, irregular margins, extrathyroidal extension
hypoechoic, Interrupted rim calcification with soft tissue extrusion
nodule with irregular margins, suspicious left lateral lymph node
Intermediate Suspicion 10%-20%
hypoechoic solid regular margin
hypoechoic solid regular margin
Low Suspicion 5%-10%
hyperechoic solid regular margin
isoechoic solid regular margin
partially cystic with eccentric solid area
partially cystic with eccentric solid areas
Very low Suspicion <3%
spongiform
partially cystic no suspicious features
partially cystic no suspicious features
Benign <1%
cyst

Ultrasound elastography is a technique that measures the stiffness of a thyroid nodule. It was originally developed with the promise of incrementally improving ultrasound's noninvasive risk assessment of malignancy. Initial results were promising, although follow-up results have been mixed on validation studies.[24] Elastography is a highly specialized technique with unique equipment, and it is most effective for only a small subset of nodules. Currently, elastography is not recommended for routine use in the evaluation of thyroid nodules, but it may be useful for selected cases in specialized centers.

Fine-Needle Aspiration Cytology

FNA biopsy is the most accurate and cost-effective invasive procedure in the workup of thyroid nodules. For all thyroid nodules, FNA has a mean sensitivity of over 80% and a mean specificity of over 90%. Although FNA can technically be performed without ultrasound guidance for palpable nodules, the accuracy overall with ultrasound assistance is superior. FNA is performed with a small-gauge needle (typically 23–27 gauge), and it may be performed with capillary or suction techniques. Ideally, the adequacy of the specimen can be confirmed at the time of the procedure with on-site cytopathologic evaluation. The excellent discriminatory ability and extremely low complication rate of FNA have rendered biopsy methods with larger-bore needles such as core-needle biopsy obsolete.

The indications for FNA biopsy are described in greater detail earlier and are largely dependent on the risk profile of the thyroid nodule on ultrasound. For example, FNA would be recommended for higher-risk pattern nodules classified as ATA high-suspicion or TI-RADS TR5; in other words, solid hypoechoic nodules with microcalcifications that are at least 1 cm should be considered for biopsy, whereas very low-risk nodules that are spongiform have higher size cutoffs for biopsy or can be observed. Risk factors other than sonographic profile can reduce the threshold for performing FNA biopsy, including positive family history of thyroid cancer, history of significant radiation exposure, and PET-positivity. FNA should only be performed if the results would influence patient management. For instance, small- to moderate-sized thyroid nodules in the extreme elderly or those with prohibitive surgical risk, or in patients without other concerning features who are already proceeding with thyroidectomy, do not require FNA.

Historically, cytologic findings from FNA were broadly categorized into three categories: benign, malignant, and indeterminate. Although this system was generally helpful for the majority of thyroid nodules with highly predictive benign and malignant features, its drawbacks included (1) significant variability in pathology evaluation and reporting and (2) inability to more finely discriminate features within the broadly termed "indeterminate" category. To address these limitations, the National Cancer Institute convened a State of the Science conference in 2007 to develop a consensus for cytologic terminology known as the *Bethesda System for Reporting Thyroid Cytopathology;* an updated third version was published in 2023 and is described here.[25] This system formalized six diagnostic categories of FNA cytology, with an estimation of cancer risk associated with each category based on literature review and expert opinion. These categories, in increasing numerical order, are (1) nondiagnostic/unsatisfactory, (2) benign, (3) atypia of undetermined significance (AUS), (4) follicular neoplasm (FN), (5) suspicious for malignancy, and (6) malignant (Fig. 73.17). Table 73.3 provides a breakdown of these categories and their associated malignancy risk in addition to the possible changes in malignancy risk if the histopathologic diagnosis of noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP; see later) were no longer to be included as a malignancy.

The broad institution of the Bethesda classification system across virtually all major centers has led to significant improvements in standardization of care, communication of cancer risk with other clinicians and patients, and research efforts. Validation studies in large numbers of patients have shown overall good concordance in the FNA reporting patterns and malignancy rates. However, there is significant variability in the risk of malignancy in each category, particularly in the AUS category.[26] This has led to the recommendation for each individual institution to define its own patient population's malignancy risks for each of the Bethesda categories by correlating cytology to surgical histopathology from surgical specimens.

Molecular Testing of Fine-Needle Aspiration Specimens

Although no FNA cytology can completely rule out or rule in malignancy in a thyroid nodule, the cytologic diagnoses of benign (Bethesda category II) and malignant (Bethesda VI) are highly accurate with an error rate of less than 3%. On the other hand, the remaining "indeterminate" categories—particularly AUS and follicular neoplasm (Bethesda III and IV, respectively)—are associated with a cancer risk anywhere from 6% to 40%, with Bethesda III nodules falling in the 6% to 30% range and the Bethesda IV nodules in the 10% to 40% range. Bethesda V lesions (suspicious for malignancy) are also technically indeterminate, but because these are associated with a 50% to 75% risk of malignancy, they are typically managed similarly to malignant (Bethesda VI) cytology.

Traditionally, the malignancy risk associated with Bethesda III or IV cytology in a thyroid nodule led to the recommendation of diagnostic thyroid lobectomy, but because the majority of these nodules are still ultimately benign on final pathology, efforts have been made in molecular genetics to improve prediction capability and reduce the number of unnecessary thyroidectomies. Advancements in molecular genetics have enabled the creation of relatively affordable high-throughput DNA- or RNA-based assays for creating molecular profiles or signatures of cytology samples that would provide more accurate assessment of malignancy risk in thyroid nodules. There are multiple commercial providers for these tests, but the two most prominent tests are the Afirma (Veracyte, San Francisco, CA) and ThyroSeq (CBLPath, Rye Brook, NY).

The Afirma product was the first molecular test commercially available in this space. Its first-generation assay, the Gene Expression Classifier, employed proprietary machine learning algorithms on a 167-gene mRNA microarray to separate nodules' gene expression signatures into "benign" and "suspicious" categories. The Gene Expression Classifier test's accuracy was first evaluated in 2012 in a study of surgically excised thyroid nodule specimens, and it was found to demonstrate excellent sensitivity and NPV (90% and ~95%, respectively), but with relatively poor specificity and positive predictive value (PPV; ~50% and 38%, respectively) for Bethesda III and IV nodules. Subsequent studies have largely validated the original study's findings, but many of them have been limited by the lack of a true negative (i.e., benign) reference standard.[27]

TABLE 73.3 The 2023 Bethesda System for Reporting Thyroid Cytopathology Implied Risk of Malignancy and Recommended Clinical Management

DIAGNOSTIC CATEGORY (BETHESDA NUMBER)	RISK OF MALIGNANCY IF NIFTP ≠ CANCER	RISK OF MALIGNANCY IF NIFTP = CANCER	USUAL MANAGEMENT
Nondiagnostic (I)	5%–18%	5%–20%	Repeat FNA with ultrasound guidance
Benign (II)	0%–4%	2%–7%	Clinical and sonographic follow-up
AUS (III)	6%–24%	~13%–30%	Repeat FNA, molecular testing, or lobectomy
FN (IV)	17%–28%	23%–34%	Molecular testing or lobectomy
Suspicious for malignancy (V)	58%–74%	67%–83%	Near-total thyroidectomy or lobectomy
Malignant (VI)	94%–96%	97%–100%	Near-total thyroidectomy or lobectomy

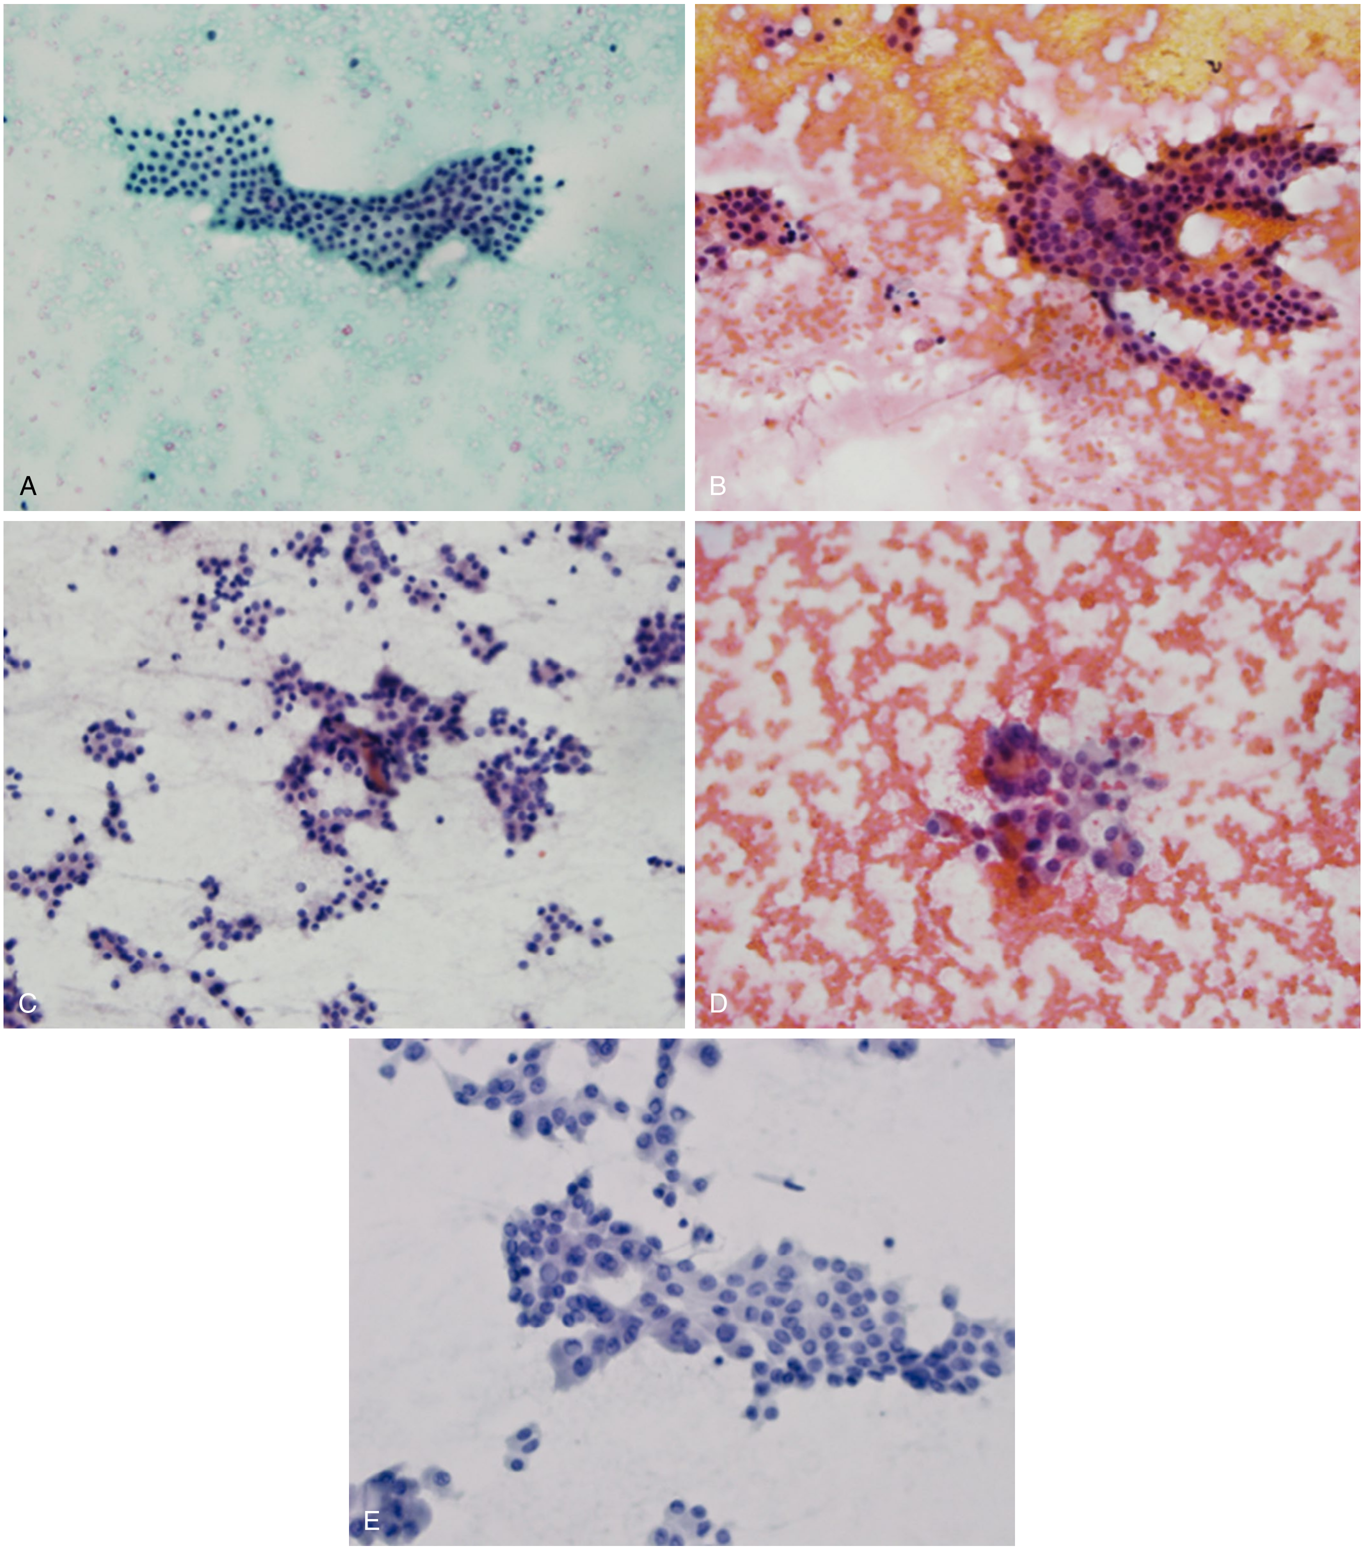

FIGURE 73.17 Representative cytologic features of thyroid fine-needle aspiration specimens arranged according to the Bethesda classification for prediction of malignancy. (A) Category II: benign colloid nodule with bland-appearing follicular cells arranged in a macrofollicular pattern and abundant colloid in the background. (B) Category III: atypia of undetermined significance; follicular cells show nuclear enlargement of most nuclei with occasional intranuclear grooves. (C) Category IV: follicular neoplasm with highly cellular aspirate composed of uniform follicular cells arranged in microfollicles. (D) Category V: suspicious for papillary thyroid cancer (PTC); these representative microfollicular groups show nuclear enlargement and pale chromatin and rare intranuclear grooves and pseudoinclusions. (E) Category VI: PTC demonstrating a large sheet of neoplastic cells with enlarged oval "Orphan Annie eye" nuclei; multiple intranuclear pseudoinclusions are also present. (Courtesy Elham Khanafshar, MD, MS, Department of Pathology and Laboratory Medicine, University of California, San Francisco.)

To address its limitations as a "rule-in" test because of its poor specificity and PPV, the newest Afirma product, the Genomic Sequence Classifier (GSC), improved the core machine learning algorithm for its larger gene expression array of 10,196 genes and included seven other upstream components, evaluating for a number of genetic mutations highly specific for malignancy. The performance of the GSC was recently evaluated in a multi-institutional blinded validation study on 191 cytology samples from 183 patients. For Bethesda III and IV lesions, the GSC demonstrated incremental improved performance compared with the Gene Expression Classifier, with sensitivity, specificity, NPV, and PPV of 91%, 68%, 96%, and 47%, respectively, based on a 24% cancer prevalence. Oncocytic neoplasms remained an area of weakness in the GSC; it accurately predicted oncocytic adenomas and carcinomas of the thyroid in only 10/17 and 1/9 specimens, respectively.[27]

The ThyroSeq product approaches molecular classification differently from Afirma, in that it employs next-generation DNA sequencing technology to detect the presence or absence of a discrete list of known gene mutations and gene fusions associated with thyroid cancer. This technology is based on work described by Nikiforov and colleagues[28] at the University of Pittsburgh, and the second version of the product (termed v2) evaluating 13 mutations and 42 fusions demonstrated promising results in their single-institution studies, with sensitivities and specificities in the low 90% range, PPV in the high 60% to 80% range, and NPV over 95%. These initial data originally generated excitement that perhaps the ThyroSeq v2 would offer ideal accuracy characteristics because the PPV appeared to approximate that of Bethesda V cytology while maintaining excellent NPV; however, subsequent validation studies showed less impressive results.[29]

The newest-generation ThyroSeq product (termed v3) improves the number of genes in its mutational panel and incorporates other genetic information, such as changes in gene copy number as well as some gene expression data. Steward and colleagues[29] conducted a prospective, blinded, multicenter study of the ThyroSeq v3 in 286 cytologically indeterminate FNA samples with known surgical pathology results. In Bethesda III and IV nodules, the test had a sensitivity and specificity of 94% and 82%, respectively, and an NPV and PPV of 97% and 66%, respectively, based on a cancer/NIFTP prevalence of 28%. Importantly, the test correctly predicted Hürthle cell (now oncocytic) adenomas and carcinomas in 62% and 100% of cases, respectively.[29]

The early data for both the Afirma GSC and ThyroSeq v3 suggest promising improvements over previous-generation products, and subsequent management guidelines for thyroid nodules will likely incorporate molecular testing to a greater degree. Ultimately, the decision whether or not to use molecular testing needs to be placed in the context of other variables that go into clinical decision-making. First, whether to proceed with thyroidectomy may rest on factors other than the results of an FNA biopsy, let alone molecular testing. Second, the price of these assays is not insignificant, and their institutional setting–specific incremental value and cost-effectiveness must be considered. Third, patients should be counseled about the inherent uncertainties in the therapeutic and long-term clinical implications of pursuing molecular testing.

THYROID CANCER

Thyroid cancers are generally classified into DTC, PDTC, MTC, and ATC. Other thyroid malignancies, including primary thyroid lymphoma, thyroid sarcoma, and metastases to the thyroid gland, are rare. DTCs consisting of PTC, FTC, and OCA are considered "differentiated" because they arise from the thyroid follicular epithelial cells and generally retain the ability to organify iodine. PDTC and ATC are also thought to arise from follicular cells but are more clinically aggressive compared with DTC because of their loss of differentiation. MTC, unlike the other tumors described, arise from the neuroendocrine parafollicular C cells.

DTC makes up the vast majority of thyroid cancers, with PTC and FTC representing 84% and 11%, respectively, of all thyroid cancer diagnoses. MTC represents 2%, and ATC occurs in 1% of all cases. Thyroid cancer overall carries an excellent prognosis, primarily because of the predominance of PTC, whereas ATC is among the most aggressive and lethal solid tumors of any organ system, with a nearly 100% mortality rate.

Incidence

Approximately 54,000 new cases of thyroid cancer are diagnosed each year in the United States, with over 2000 annual deaths. There is a more than threefold female predominance in incidence, and over the last several decades, thyroid cancer became the fastest-growing cancer among American females, with an incidence that tripled in the United States; similarly dramatic increases were seen in other developed and developing countries throughout the world.[30] Whereas many authors attributed the vast majority of the increase to overdiagnosis given overall stability of mortality rates at 0.5 deaths per 100,000, a more recent review of the same dataset revealed substantial increases in the incidence of larger and advanced-stage PTC concomitant with the increase in the smaller and likely more indolent tumors.[31] Specifically, Lim and colleagues found that the incidence-based mortality actually increased both overall in all PTCs and particularly in the advanced-stage tumors, suggesting that there was in fact a true increase in the occurrence of thyroid cancer.[31] Although incidence of distant metastatic disease in DTC has increased over the last several decades, survival for these patients remains static at only 50% 10 years after diagnosis.[32] As the 2009 and 2015 ATA Guidelines for DTC have generally recommended less aggressive management to avoid treatments with fewer benefits than risks, recent analysis has shown that the proportion of patients receiving thyroidectomy alone without postoperative RAI has increased from 2006 to 2018.[33] Performance of thyroid lobectomy increased only slightly from 2015 to 2018, potentially indicating that clinicians are exercising more caution about its utility. It is likely that the rate of lobectomy will increase in the coming years as more data and guidelines emerge supporting its use.

Differentiated Thyroid Cancer

The primary cancers arising from the thyroid follicular epithelial cells are PTC, FTC, and OCA. Despite some differences in biologic and clinical behavior, DTCs are generally approached and managed similarly.

PTC, as mentioned earlier, is the most common type of thyroid cancer overall, comprising 84% of all incident cases. There is a female predominance, with a 3:1 female-to-male ratio, and peak incidence is in the third to fifth decades of life. PTC disseminates primarily via the lymphatic route and affects the cervical lymph nodes in the central and lateral compartments (see later); however, distant metastases do occur in up to 3% to 5% of patients, typically to lung and bone. Histologically, PTC is characterized by complex branching papillae with pseudoinclusions, nuclear grooving, and psammoma bodies (Fig. 73.18A). The so-called

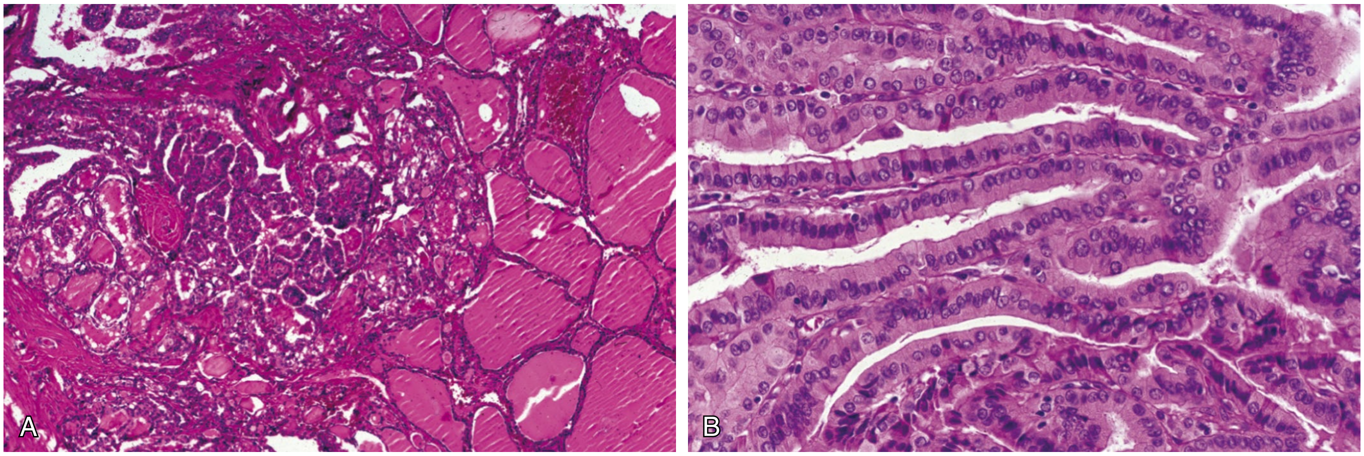

FIGURE 73.18 (A) Hematoxylin and eosin (H&E) staining of a thyroid mass reveals papillary projections consistent with papillary thyroid cancer (PTC). (B) H&E staining of PTC shows cells with an increased height-to-width ratio in a single row of cells. This is the so-called tall cell variant of PTC, which is associated with a poorer prognosis than well-differentiated PTC.

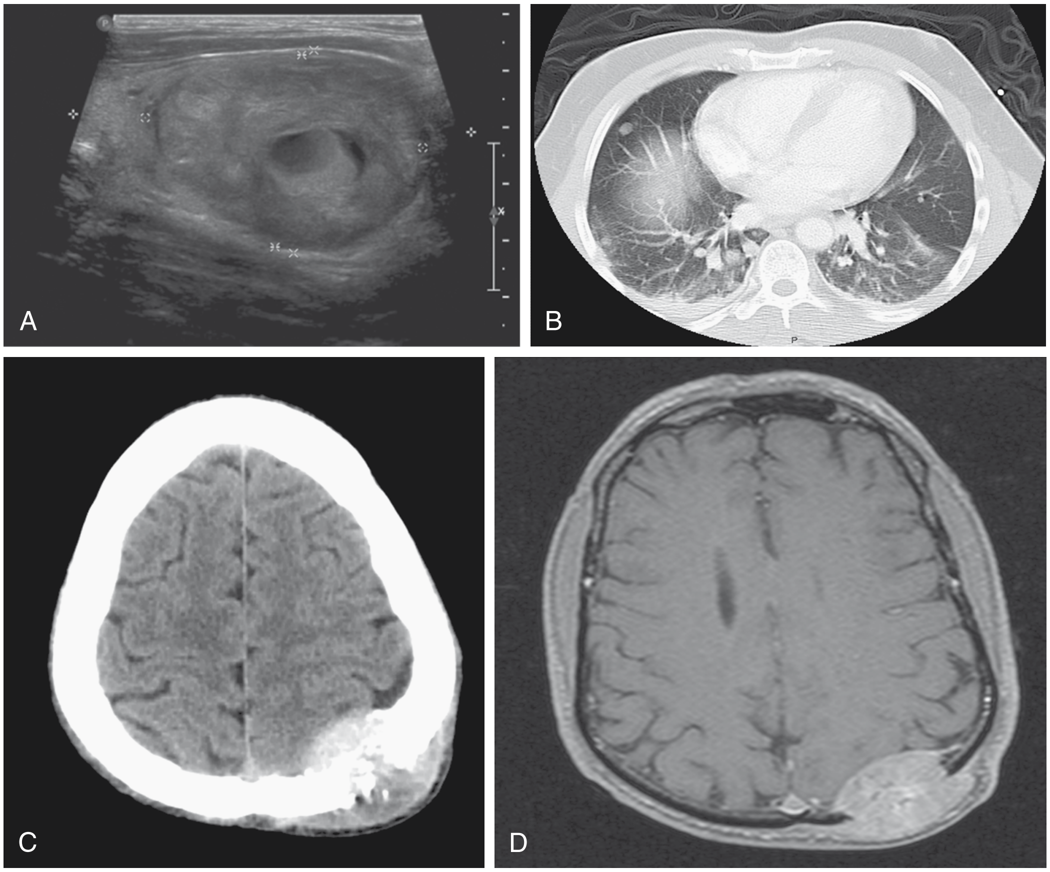

FIGURE 73.19 Metastatic follicular thyroid cancer (FTC); all images are from the same patient. (A) Preoperative ultrasound demonstrates a 6.7-cm mass in the left lobe of the thyroid; pathology demonstrated FTC. (B) Computed tomography (CT) image of the chest demonstrates multiple pulmonary metastases. (C) CT image of the head demonstrates left parietal bone metastasis. (D) Magnetic resonance imaging of the head demonstrates left parietal bone metastasis with an epidural component and mass effect on the brain.

follicular variant of PTC (fvPTC) has a similar prognosis to classical PTC and histologically has well-defined follicles with minimal papillary projections. Other less common but more aggressive histologic subtypes of PTC include tall cell (see Fig. 73.18B), hobnail, diffuse sclerosing, and columnar variants, which together comprise less than 1% of all PTCs.

FTC is the second most common type of DTC. FTC occurs in older adults, with peak incidence in the fourth and sixth decades. As in the case of PTC, the incidence of FTC is female-predominant, with a 3:1 female-to-male ratio. In contrast to that of PTC, the pattern of spread of FTC is hematogenous, typically to the lungs and bone (Fig. 73.19). Regional nodal metastases occur in less than 10% of cases. Cytologically, FTC can range from having virtually normal-appearing follicular cells to those with various abnormal features, including nuclear atypia, discohesion, hypercellularity, and microfollicles; thus, FTC cannot be reliably diagnosed by FNA. FTC can only be definitively diagnosed on histologic examination based on the presence of capsular and/or vascular invasion (Fig. 73.20A).

OCA is a new term in the 2022 World Health Organization classification of thyroid neoplasms, replacing the misnomer Hürthle cell carcinoma, to designate invasive, malignant follicular cell neoplasms with at least 75% oncocytic cells (see Fig. 73.20B).[21] It is less common, accounting for 5% of DTCs in the United States. OCA occurs in older adults, with peak incidence in the sixth and seventh decades. Metastases can occur via lymphatic and hematogenous routes, and distant metastases are present in up to 20% of patients at initial diagnosis. Five-year overall survival is about 85%, but only 24% for patients with distant metastases at diagnosis. OCA is less RAI-avid compared with other DTCs, which makes OCA more difficult to treat if there is disease recurrence. RAI treatment is potentially associated with improved survival in patients with OCAs that are 2 to 4 cm.

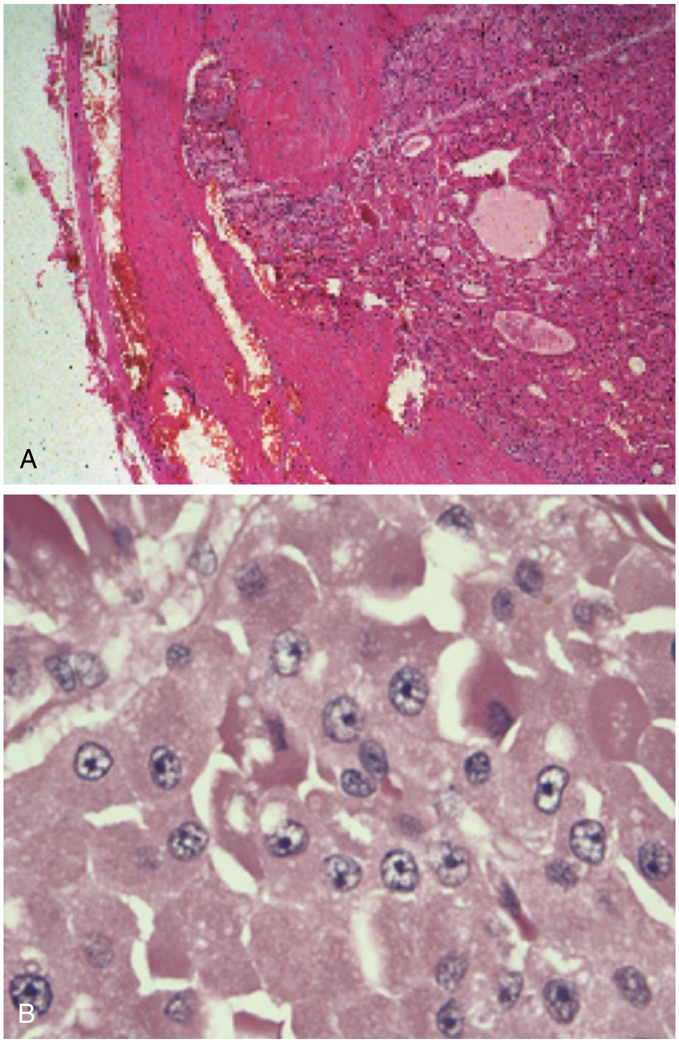

FIGURE 73.20 (A) Hematoxylin and eosin (H&E) staining of a follicular lesion. High-power examination reveals capsular invasion by follicular cells, which is consistent with a diagnosis of follicular thyroid cancer. (B) H&E staining of oncocytic carcinoma of the thyroid showing vesicular nuclei with irregular macronucleoli. (From Freeman JL, Kim DS. Hürthle cell tumors of the thyroid. In: Randolph GW, ed. *Surgery of the Thyroid and Parathyroid Glands 2.* Philadelphia: Elsevier Saunders; 2013:207.)

Low-Risk Follicular Thyroid Neoplasms

The 2022 WHO classification of thyroid neoplasms has three distinct categories: benign, low-risk, and malignant.[21] Low-risk follicular thyroid neoplasms include noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP), thyroid tumors of uncertain malignant potential (UMP), and hyalinizing trabecular tumor (HTT). Low-risk neoplasms have the potential to metastasize, but the incidence of metastasis is extremely low.

Historically, NIFTP was known as the noninvasive encapsulated follicular variant of papillary thyroid cancer (fvPTC). In 2016, a multidisciplinary group of thyroidologists performed a pivotal retrospective analysis of 109 patients with the encapsulated variant and 101 patients with invasive fvPTC; patients had a median follow-up period of 13 years (range, 10–26 years) for the encapsulated variant group and 3.5 years (range, 1–18 years) for the invasive fvPTC group. The authors found that none of the patients with encapsulated fvPTC died or had evidence of disease after treatment, compared with a 12% rate of adverse oncologic outcomes in the invasive fvPTC cohort. Based on these findings, the authors proposed a change in terminology from encapsulated fvPTC to "noninvasive follicular thyroid neoplasm with papillary-like nuclear features," or NIFTP (Fig. 73.21), with the goal being to more accurately reflect the indolent nature of this tumor as well as to deemphasize the connotations of malignancy from the name.[34] Thyroid lobectomy is considered adequate treatment for NIFTP, and further treatment such as TSH suppression or RAI is not required.[35]

HTTs are well-demarcated thyroid nodules with PTC-like nuclear changes, but they demonstrate a unique intratrabecular hyaline material that is not seen in other neoplasms. Also, HTT has a distinct molecular change: *GLIS* gene rearrangements define HTT and are not found in other thyroid neoplasms. HTT almost

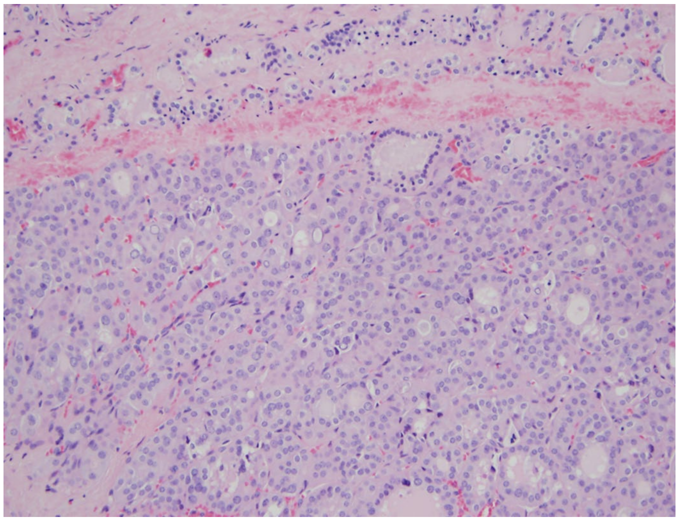

FIGURE 73.21 Noninvasive follicular thyroid neoplasm with papillary-like nuclear features is a well-circumscribed/encapsulated microfollicular-pattern neoplasm with no capsular or vascular invasion. (Courtesy Elham Khanafshar, MD, MS, Department of Pathology and Laboratory Medicine, University of California, San Francisco.)

always follows a benign course; therefore, thyroid lobectomy is considered adequate treatment. In general, thyroid lobectomy with clinical and imaging surveillance is favored for NIFTP and HTT because they almost always follow a benign course. However, UMP tumors require closer follow-up because their metastatic potential is uncertain.

Thyroid Follicular Cell Neoplasia and Oncogenesis

The two major molecular pathways governing thyroid follicular cell oncogenesis are the mitogen-activated protein kinase (MAPK) signaling and the phosphatidylinositol 3-kinase/protein kinase B (PI3K/AKT) pathways (Fig. 73.22). Together, these pathways govern normal thyroid cell survival and function; perturbations at multiple points in these pathways have been directly linked to the pathogenesis of thyroid cancer. In 2014, the Cancer Genome Atlas project consortium published its results from a comprehensive, multiplatform, next-generation genomic sequencing analysis of 496 PTCs.[36] This seminal study confirmed the dominant and typically mutually exclusive roles of driving somatic genetic alterations in the MAPK and PI3K/AKT pathways in PTC. The results of the Cancer Genome Atlas are estimated to have increased the proportion of PTCs that can be identified based on molecular signature using current genome sequencing technology from 75% to over 96%. This has translated into improved molecular testing methods to facilitate the preoperative diagnosis of thyroid cancer (see earlier).

The MAPK signaling pathway is activated by growth factors binding to cell-surface transmembrane tyrosine kinase receptors. This triggers an intracellular signaling cascade that ultimately regulates the intranuclear transcription of genes responsible for cellular growth/proliferation, differentiation, migration, and survival. In the MAPK pathway, the proto-oncogene *BRAF* is most frequently mutated in PTC; it is typically a point mutation with a glutamate-for-valine substitution at residue 600 (p.V600E). The *BRAFV600E* mutation occurs early in oncogenesis, resulting in dedifferentiation and tumor growth. This mutation is found in up to 60% of all PTCs. The second most common type of mutations found in PTC involve the RAS family of genes. These mutations

occur in 20% to 30% of PTCs and are more common in fvPTCs. Unlike BRAF, RAS can activate both the MAPK and PI3K-AKT pathways.

The PI3K/AKT pathway, like the MAPK pathway, involves a series of phosphorylation reactions, starting with a transmembrane protein kinase. This leads to the activation of AKT, which in turn phosphorylates proteins both in the cytosol and the nucleus. Downstream targets of AKT regulate apoptosis, proliferation, cell-cycle progression, cytoskeletal integrity, and energy metabolism. This pathway is thought to be particularly relevant to the development of FTC; further supporting this theory is the finding that mutations in *PTEN* (an inhibitor of AKT activation) are found in both sporadic FTC and FTC associated with Cowden syndrome (a hereditary disorder characterized by multiple hamartomas—particularly of the skin and mucous membranes—macrocephaly, and an increased risk of other solid organ cancers such as breast, endometrial, and colorectal cancer).

Rearrangements of the *RET* proto-oncogene, which are present in 5% to 10% of all PTCs, are characteristic of PTCs linked to radiation exposure. These translocations result in the kinase domain of RET being fused with another protein, most commonly CCDC6, resulting in a constitutively active kinase that triggers carcinogenesis through MAPK and PI3K/AKT activation. *RET*-rearranged PTCs are associated with more aggressive features, including multifocal tumors, extrathyroidal extension, and distant metastases, than *BRAFV600E* or *RAS* mutant tumors.[37]

Telomerase reverse transcriptase *(TERT)* promoter mutations are found in up to 27% of PTCs and especially in those that also have mutations affecting the MAPK pathway, such as *RAS* mutations and *BRAFV600E*. *TERT* promoter mutations upregulate expression of TERT, enabling unlimited cellular proliferation. *TERT* mutations are associated with aggressive clinical and histologic features as well as RAI resistance and high risk of cancer recurrence, especially when present with *BRAF* mutation.

Risk Factors

The two most studied and validated risk factors for PTC include a history of ionizing radiation exposure and a family history of DTC.

The association of ionizing radiation exposure in childhood and adolescence in particular is clear for PTC and perhaps ATC.[38] Acute environmental exposures from catastrophic occurrences, such as the Chernobyl nuclear accident and nuclear bombings in Hiroshima and Nagasaki, have dramatically demonstrated the impact of radiation on thyroid follicular cell oncogenesis. Atomic bomb survivors in Japan have been found to have an increased risk of thyroid nodules and PTC up to 50 years after the incident, with a linear radiation dose response. Medical sources of irradiation, such as external beam radiation therapy to the head and neck as well as historical practices such as radiation therapy in the 1950s and 1960s for acne and tonsillitis, also have been linked to the subsequent development of PTC. Children and adolescents are particularly vulnerable, with even low-dose radiation exposure (e.g., equivalent to a single chest x-ray) increasing PTC risk in a dose-dependent fashion.

A strong family history of DTC has also been shown to increase the risk of DTC. Known hereditary cancer syndromes with specific single-gene mutations are associated with higher incidence of DTC: familial adenomatous polyposis (which predisposes to PTC), Gardner syndrome (PTC), Cowden syndrome (FTC and occasionally PTC), Carney complex (PTC and FTC), and Werner syndrome (PTC and FTC). In addition, a separate entity known as *familial non-MTC* was coined to describe families with two or more first-degree relatives diagnosed with DTC in the absence of other hereditary cancer syndromes. Familial non-MTC tumors are thought to be more aggressive and portend a worse prognosis than their sporadic counterparts.[39] However, the exact inheritance pattern and genetics underlying familial non-MTC remain poorly understood.

Obesity also has consistently been identified as a risk factor for DTC.[38] There has been a close parallel increase in the trends of obesity prevalence and the incidence of thyroid cancer. A pooled analysis of 22 prospective studies found that thyroid cancer risk was associated with multiple markers of obesity, including waist circumference, body mass index (BMI), and BMI gain between young adulthood and study baseline. Kitahara and colleagues analyzed the National Institutes of Health (NIH)–AARP Diet and Health Study data to show that overweight and obesity may have contributed to one out of every six new PTC cases in patients older than 60 by 2015.[40] In addition, PTCs in obese patients have been associated with more aggressive tumor characteristics.

Other environmental exposures have been hypothesized to increase the risk of DTC. Hoffman and colleagues[41] published a case-control study of patients with PTC and demonstrated a link between the levels at home of certain common flame-retardant chemicals to increased odds of PTC, particularly decabromodiphenyl ether and tris(2-chloroethyl) phosphate. An increased risk of DTC also has been reported in clusters of volcanic areas around the world, including Hawaii, Iceland, French Polynesia, New Caledonia, and Sicily; this may be the result, in part, of exposure to heavy metals and other toxic compounds from gas, ash, and lava emissions from volcanoes that contaminate ground water and food sources.[42] The underlying mechanisms for all of these potential environmental carcinogens remain unclear and require further study.

Clinical Presentation

The classic presentation of DTC is that of an asymptomatic, palpable thyroid nodule discovered by either patients or physicians during routine examination. Palpable thyroid nodules are present in approximately 5% of the population, the majority of which are benign. With the improvements in high-resolution ultrasonography and other imaging modalities, thyroid nodules—and by extension thyroid cancer—have become more commonly diagnosed in asymptomatic individuals, as described earlier.

DTCs are typically slow-growing, painless, and often asymptomatic. Acute pain is more typical of a benign process such as thyroiditis or an acute bleed into a benign cyst; however, pain can also be indicative of less common and more aggressive thyroid cancers such as MTC, primary thyroid lymphoma, and ATC. Concerning features include rapid growth of the nodule and symptoms such as hoarseness, coughing, or dysphagia, which could signal local invasion into surrounding structures such as the RLN and aerodigestive tract (Fig. 73.23).

On physical examination, palpable DTC can vary from soft to firm in texture on palpation. Firm and fixed masses may suggest locally advanced disease. Patients may have palpable or imaging-detected cervical lymphadenopathy.

Imaging Workup

To adequately inform initial surgical treatment, the quality of preoperative imaging is paramount. The most important imaging

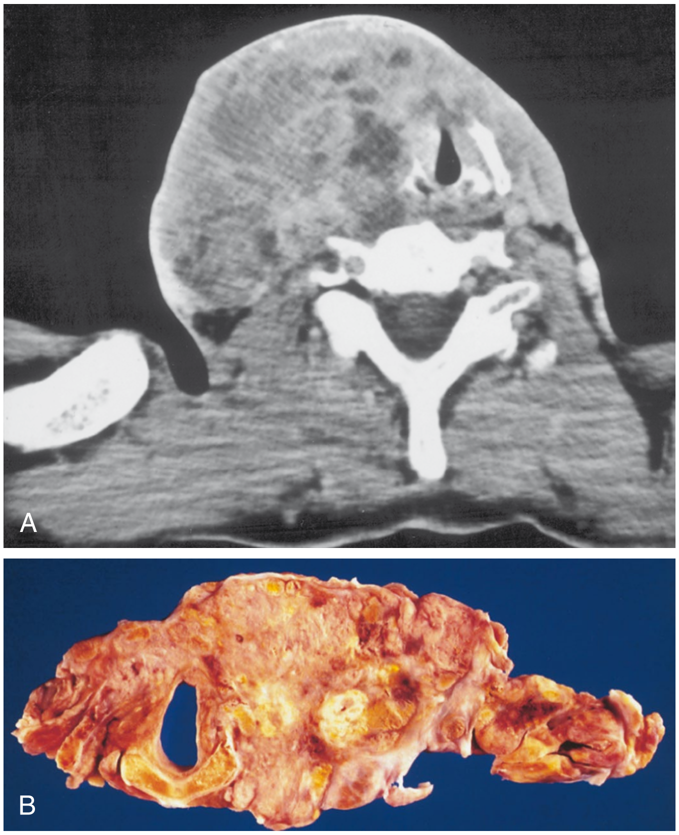

FIGURE 73.23 (A–B) Rapidly enlarging thyroid mass in a 70-year-old patient. Computed tomography image demonstrates displacement of the larynx and lateral involvement of both jugular veins. The patient died within 6 months of rapidly progressing follicular thyroid cancer.

modality for surgical planning is comprehensive thyroid ultrasound with lymph node mapping of the bilateral central and lateral neck compartment lymph nodes. Preoperative ultrasound is the most sensitive test for the characterization of thyroid nodules as well as identification of pathologic lymphadenopathy, with its results affecting the extent of initial surgical therapy in over 30% of patients.

Cross-sectional imaging (contrast-enhanced CT or MRI of the neck and chest) and intraluminal imaging (laryngoscopy, bronchoscopy, or esophagoscopy) may be required in patients with potentially more advanced local and regional disease. Clinical manifestations that may lead the clinician to obtain these additional studies include concerning symptoms such as voice changes and dysphagia; respiratory symptoms such as cough or hemoptysis; and palpable evidence of rapidly enlarging, bulky, and/or fixed disease on physical examination. Sonographic indications include evidence of bulky disease, disease extending into the chest or extending posteriorly, and extrathyroidal extension.

The routine use of PET scanning in preoperative planning is not recommended.

Staging

There have been many proposed staging systems over the years for estimating disease-specific mortality from DTC, but the American Joint Committee on Cancer (AJCC) and Union for International Cancer Control Tumor, Node, Metastasis (TNM) classification has emerged as the most widely accepted and easily understood. The current 8th edition of the TNM system, which took effect in early 2018, is summarized in Table 73.4. The 8th edition has made a number of major changes that better optimize prediction and stratification of patient survival.[43] These include the following:

1. The age cutoff for staging, which was originally established to reflect the survival benefit of younger age, was increased from 45 to 55 years at diagnosis.
2. Minimal extrathyroidal extension detected only on histologic examination—as opposed to gross extrathyroidal extension—was removed from the definition of T3 disease, effectively eliminating this factor from staging.
3. N1 (regional nodal) disease no longer upstages a patient ≥55 years to stage III.
4. T3a is a new category for tumors >4 cm confined to the thyroid gland.
5. T3b is a new category for tumors of any size demonstrating gross extrathyroidal extension into the strap muscles.
6. Level VII lymph nodes were reclassified as central neck lymph nodes (N1a) as opposed to lateral neck lymph nodes to be more anatomically consistent.
7. The presence of distant metastases in patients ≥55 years was reclassified from stage IVC to stage IVB.

The downstream effect of the changes made to the 8th edition is to downstage many patients; as a result, patients with higher-stage disease experience a worse prognosis in the new system, thus better discriminating prognosis between stages and more accurately reflecting the overall relatively low risk of thyroid cancer mortality. Under the 8th edition, the estimated disease-specific survival in younger patients is expected to be 98% to 100% for stage I and 85% to 95% for stage II, and in older patients >55 years 98% to 100%, 85% to 95%, 60% to 70%, and less than 50% for stage I, II, III, and IV disease, respectively.[44]

Although systems such as TNM are important for making initial estimates of disease-specific mortality, the fact remains that the vast majority of patients will have excellent long-term survival. Therefore, what is arguably more clinically relevant to patients with DTC is the risk of disease recurrence, which is an outcome that systems such as TNM are not designed to measure. In response, the ATA proposed in its 2009 guidelines a system for estimating the initial risk of recurrence based on a number of clinicopathologic features, with a three-tiered risk classification that stratified patients into low-risk (~3%), intermediate-risk (~21%), and high-risk (~68%) categories.[45] In the 2015 updated guidelines, it was acknowledged that even within these three tiers, the level of risk depends on many individual tumor

TABLE 73.4 Summary of the AJCC 8th Edition Staging System for DTC

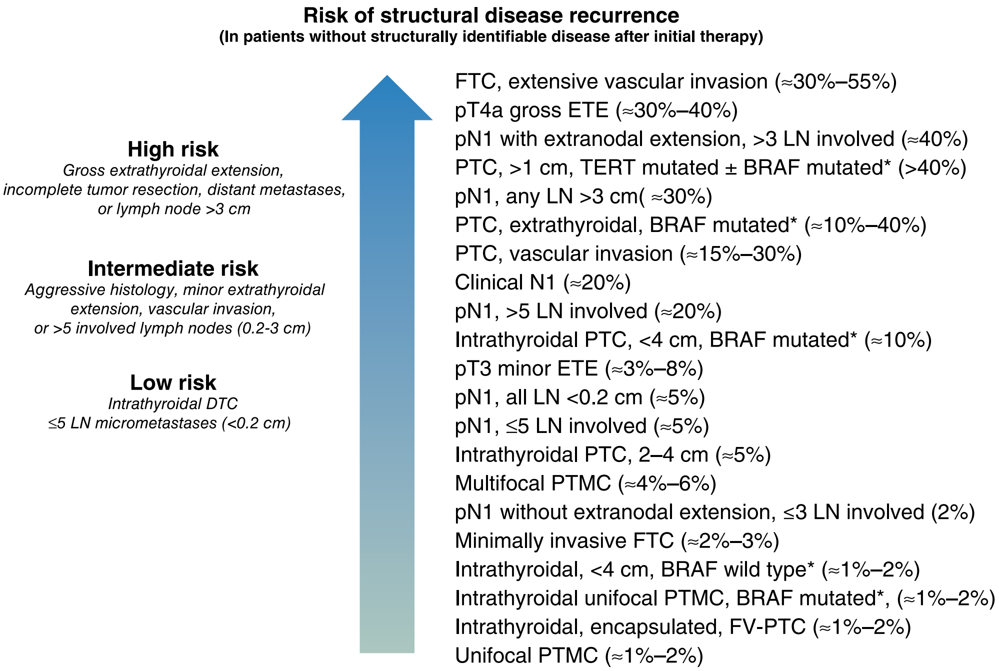
Data from Amin MB, Edge SB, Greene FI, et al. *AJCC Cancer Staging Manual*. 8th ed. New York: Springer; 2018.



Risk of structural disease recurrence
(In patients without structurally identifiable disease after initial therapy)
High risk
Gross extrathyroidal extension, incomplete tumor resection, distant metastases, or lymph node >3 cm
Intermediate risk
Aggressive histology, minor extrathyroidal extension, vascular invasion, or >5 involved lymph nodes (0.2-3 cm)
Low risk
Intrathyroidal DTC
≤5 LN micrometastases (<0.2 cm)
FTC, extensive vascular invasion (≈30%–55%)
pT4a gross ETE (≈30%–40%)
pN1 with extranodal extension, >3 LN involved (≈40%)
PTC, >1 cm, TERT mutated ± BRAF mutated* (>40%)
pN1, any LN >3 cm(≈30%)
PTC, extrathyroidal, BRAF mutated* (≈10%–40%)
PTC, vascular invasion (≈15%–30%)
Clinical N1 (≈20%)
pN1, >5 LN involved (≈20%)
Intrathyroidal PTC, <4 cm, BRAF mutated* (≈10%)
pT3 minor ETE (≈3%–8%)
pN1, all LN <0.2 cm (≈5%)
pN1, ≤5 LN involved (≈5%)
Intrathyroidal PTC, 2–4 cm (≈5%)
Multifocal PTMC (≈4%–6%)
pN1 without extranodal extension, ≤3 LN involved (2%)
Minimally invasive FTC (≈2%–3%)
Intrathyroidal, <4 cm, BRAF wild type* (≈1%–2%)
Intrathyroidal unifocal PTMC, BRAF mutated*, (≈1%–2%)
Intrathyroidal, encapsulated, FV-PTC (≈1%–2%)
Unifocal PTMC (≈1%–2%)

FIGURE 73.24 The risk of structural disease recurrence for differentiated thyroid cancer after initial therapy exists on a continuum of risk estimates. The three-tiered American Thyroid Association modified initial risk stratification system is shown in the left-hand column. *ETE,* Extrathyroidal extension; *FTC,* follicular thyroid cancer; *FV-PTC,* follicular variant papillary thyroid cancer; *LN,* lymph node; *PTC,* papillary thyroid cancer; *PTMC,* papillary thyroid microcarcinoma. (From Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association management guidelines for adult patients with thyroid nodules and differentiated thyroid cancer: the American Thyroid Association Guidelines Task Force on Thyroid Nodules and Differentiated Thyroid Cancer. *Thyroid.* 2016;26:1-133.)

characteristics and actually exists on a continuum (Fig. 73.24). Molecular testing and profiling will likely enhance clinical staging systems.

The ATA guidelines have proposed a system that dynamically changes the initial risk estimates based on the clinical course of disease and response to therapy.[19] The four response-to-initial-therapy categories in this system include the following:

1. “Excellent response”: no clinical, biochemical, or structural evidence of disease (translating to a 1%–4% risk of recurrence)
2. “Biochemical incomplete response”: abnormal Tg or rising anti-Tg antibody levels in the absence of localizable disease (translating to 50% achieving no-evidence-of-disease status either spontaneously or with additional therapy and a 20% risk of developing structural disease)
3. “Structural incomplete response”: persistent or newly identified locoregional or distant metastases (disease-specific mortality as high as 11% with locoregional disease and 50% with distant metastases)
4. “Indeterminate response”: nonspecific biochemical or structural findings that cannot be confidently classified as either benign or malignant, including patients with stable or declining anti-Tg antibody levels without definitive structural evidence of disease (15%–20% will have structural disease identified during follow-up)

Surgical Management

Surgery is the mainstay of therapy for DTC. With the appropriate choice of operation and in the hands of a high-volume surgeon (see later), thyroidectomy is extremely safe and effective. The appropriate extent of thyroidectomy depends on multiple factors, including the extent of disease and the patient’s perioperative risk, with official recommendations evolving over the past several years.

In the past, total thyroidectomy was the traditionally recommended treatment for the majority of DTCs that measure at least 1 cm. However, ipsilateral thyroid lobectomy has become an acceptable alternative to total thyroidectomy for low-risk unilateral DTCs between 1 and 4 cm without extrathyroidal extension or evidence of metastatic disease, and it is the recommended surgical option for DTCs that are less than 1 cm. This shift in recommendations resulted from data in large observational database studies demonstrating equivalent survival between selected patients undergoing either total thyroidectomy or lobectomy for DTCs between 1 and 4 cm.[46] Thus, total thyroidectomy is now the preferred evidence-based approach only for those DTCs at higher risk for recurrence and/or disease-specific mortality. Such scenarios include the following:

- Tumor ≥4 cm
- Clinically evident nodal metastases
- Gross extrathyroidal extension
- Evidence of metastatic disease
- Radiation-induced DTC
- Familial nonmedullary thyroid cancer
- Multifocal bilateral DTC

In addition to total thyroidectomy for DTCs with clinical and/or radiographic evidence of cervical lymph node metastases, therapeutic compartment-based lymph node dissection is recommended. The lymph node compartments in the neck follow a standardized nomenclature, which is shown in Fig. 73.3. The most relevant nodal stations for thyroid cancer include the central compartment (levels VI and VII), which consists of the perithyroidal lymphoadipose tissue bounded by the carotid arteries laterally, the hyoid bone superiorly, and the innominate artery inferiorly, and the lateral compartments containing the jugular groups (levels II, III, and IV) and the inferior posterior triangle (level Vb). Therapeutic lymph node dissection should be performed in patients with radiographic or clinical evidence of metastatic disease as determined either preoperatively or intraoperatively. The presence of ipsilateral central compartment nodal involvement warrants a level VI (±VII) dissection. The presence of lateral neck nodal metastases warrants both a central and lateral compartment-based neck dissection, even in the 12% of patients with skip metastases to the lateral neck (i.e., bypassing the central neck nodes). Radical neck dissection causes significant patient morbidity and is rarely necessary for oncologic purposes.

Because microscopic lymph node metastases may occur in up to 80% of patients with PTC, some investigators have suggested routine prophylactic central neck dissection during the index thyroidectomy procedure. However, because microscopic nodal disease is rarely of clinical significance, the role of prophylactic central neck dissection remains controversial. The evidence is largely based on observational data and decidedly mixed, with some studies showing a modest benefit of prophylactic central neck dissection in reducing long-term locoregional recurrence. However, central neck dissection has been associated with a higher risk of temporary and permanent hypoparathyroidism, although this effect is blunted when the operation is performed by experienced surgeons.[47] Currently, the ATA guidelines suggest that prophylactic central neck dissection should be considered for certain higher-risk patients with cN0 papillary thyroid carcinomas with more advanced primary tumors (T3 or T4) and clinically involved lateral neck nodes and/or if the information would be helpful in guiding additional therapy.

For locally invasive primary tumors involving structures such as the strap muscles, trachea, esophagus, larynx, and RLN, careful preoperative planning with cross-sectional imaging and (rarely) endoscopic studies is critical (see earlier). Consultation and assistance from allied specialties, including thoracic surgery and otolaryngology, are recommended for complex tumors requiring segmental laryngotracheal or esophageal resection. The oncologically ideal goal of gross total resection of all visible tumor should be balanced against the potential life-changing morbidity of radical resections.

Active Nonoperative Surveillance of Papillary Thyroid Cancer

Despite advances in the management of higher-risk cancers as described earlier, arguably the most striking advance in the management of DTC in the past decade has been the dramatic deescalation of treatment for smaller thyroid cancers, which now includes nonoperative active surveillance for PTmCs, tumors smaller than 1 cm.

This treatment option has been best studied in the Japanese population. The initial report published in 2010 by Ito and colleagues[48] studied 340 patients with unilateral PTmCs who underwent once- or twice-yearly ultrasound and observation/surveillance over a mean period of 74 months. The proportion of patients in whom the tumors grew by 3 mm or more was 16% at 10 years and in whom new cervical nodal metastases were detected was 3.4% at 10 years.[48] A subsequent report by the same group of 1235 patients undergoing observation showed that patients >60 years had extremely slow progression to any form of clinical disease, with an overall rate of 2.5% at 10 years. In contrast, up to 23% of younger patients progressed to clinical disease at 10 years. Importantly, those patients who initially underwent observation and eventually had surgical resection had no detectable negative perioperative or oncologic consequences from having waited for surgical rescue.

Based on the results of these landmark studies from Japan, centers in other countries have begun to study the role of active surveillance in their specific patient populations. The largest ongoing prospective trial in the United States is at the Memorial Sloan-Kettering Cancer Center, where highly selected patients with no more than 1.5-cm unifocal PTCs and PTmCs are enrolled into a regimented active surveillance program. A 2022 systemic review of active surveillance versus immediate surgery for small, low-risk DTC demonstrated similar all-cause or cancer-specific mortality, distant metastasis, and recurrence, although the authors noted that methodologic limitations prevented their making strong conclusions.[49]

When considering whether active surveillance is appropriate for a specific patient and treatment venue, several attributes must be evaluated, including tumor features and risk profile; patient demographics, long-term compliance, and patient preferences; and the experience of the medical/surgical team running the surveillance program. In addition, a significant and controversial concern in the current healthcare climate is the geography-specific cost-effectiveness implications of long-term surveillance versus surgery.[50] Further research is needed to better identify those lowest-risk patients in whom active surveillance would benefit the most, possibly with the incorporation of molecular testing.

Postoperative Thyroid-Stimulating Hormone Suppression

In many patients after thyroidectomy for DTC, TSH suppressive doses of thyroid hormone medication are recommended to prevent hypothyroidism and to reduce the risk of TSH-stimulated tumor growth and recurrence. TSH suppression has been shown to improve overall survival in patients with stage II, III, and IV cancer; however, the degree of suppression required for survival benefit remains a point of controversy, and overall, there has been a trend toward less aggressive suppression over time.[51]

The TSH goals depend on both the risk of recurrence after initial treatment and the presence of comorbid conditions that may increase the risks of hyperthyroidism, such as older age, atrial fibrillation, and osteoporosis. For patients with low- to intermediate-risk tumors, serum TSH can initially be maintained between 0.1 and 0.5 mU/L, whereas patients with high-risk tumors should be kept initially at a TSH level of <0.1 mU/L if possible. The TSH level also may be allowed to increase closer to the normal range in patients who have an excellent response to therapy.

Radioactive Iodine

RAI therapy with ^{131}I for DTC relies on thyroid follicular cells' unique ability to take up iodine (see "Normal Thyroid Physiology," earlier). DTC is generally very iodine avid, at least initially, albeit at a lesser degree than normal thyroid follicular cells because of reduced expression of the sodium-iodide symporter. Thus, RAI is a useful adjunct in the treatment of PTC and FTC—as well as certain cases of OCA—despite its relative iodine nonavidity, whereas it plays no role in cancers that do not take up iodine, such as PDTC, MTC, and ATC.

In DTC, RAI is typically administered after thyroidectomy. There are generally two broad indications for RAI. The first indication is to ablate any residual normal thyroid tissue remaining after thyroidectomy. The rationale for this is threefold: (1) the elimination of normal thyroid tissue increases the specificity of both postoperative serum Tg and subsequent ^{131}I scanning for detection of recurrent disease, (2) remnant ablation prevents subsequent de novo thyroid cancer formation in the remnant tissue, and (3) it can be used at higher doses to treat microscopic disease as adjuvant therapy to prevent clinical recurrences. The second indication for RAI is to treat clinically detectable disease that cannot be addressed by surgery.

The role for postthyroidectomy RAI has become much more selective in the past decade, largely because of convincing evidence of the lack of benefit of RAI in patient with low-risk DTC. These patients include those with intrathyroidal tumors smaller than 4 cm without high-risk histologic features or small multifocal cancers. Multiple large database studies and systematic reviews have demonstrated no benefit of RAI in these patients with respect to either disease recurrence or mortality. In 2022, a randomized controlled trial found no benefit in terms of disease-free survival for patients with low-risk PTCs treated with total thyroidectomy and RAI versus total thyroidectomy alone.[52] However, the literature suggests some benefit of RAI for intermediate-risk patients. For example, a 21,870-patient study from the National Cancer Database demonstrated a 29% reduction in the risk of death in intermediate-risk thyroid cancer, with an even greater benefit in younger patients.[53] Further research is necessary to determine the specific subgroups in the intermediate-risk category that would benefit the most. RAI is routinely recommended for high-risk cancers to potentially decrease rates of recurrence and death. When considering ^{131}I therapy, postoperative serum Tg level and neck ultrasound can be considered: The risk of persistent or recurrent disease in cases with undetectable Tg levels ($<$0.2 ng/mL with thyroid hormone replacement or $<$1 ng/mL after TSH stimulation) in the absence of Tg antibodies with a normal neck ultrasound is very low.

RAI should be administered in patients in a low-iodine state and in a setting of high TSH levels to stimulate maximal iodine uptake by thyroid tissue. Two methods of TSH stimulation exist: administration of recombinant human TSH (rhTSH) and thyroid hormone withdrawal. The dose of RAI administered depends on the risk profile of the thyroid cancer and the indication(s) for RAI. Generally, remnant ablation doses of RAI fall in the 30 to 50 mCi range, whereas treatment-level doses are typically in the 100 to 150 mCi range. As long as there is evidence that thyroid cancer remains iodine-avid, repeated treatments with RAI are appropriate, assuming acceptable toxicity profiles. Dosimetry also can be used to help guide dosing regimens that optimize therapeutic activity while minimizing toxicity. The adverse effects of RAI include sialadenitis, nasolacrimal duct obstruction, transient tumor/thyroid swelling, infertility, and development of secondary malignancies (particularly leukemia); the risks of all of these occurrences are dose dependent. The maximal cumulative lifetime exposure to RAI is somewhat controversial but generally approximates 600 mCi. Pregnancy and breastfeeding are absolute contraindications to RAI.

Adjuvant Therapies

External beam radiotherapy (EBRT) plays a limited but important palliative role for selected situations in DTC. There are no randomized clinical trials, and EBRT practice patterns vary, so many of the recommendations rely on expert opinion and single-institution studies. The main indications for EBRT include local control of unresectable locally advanced macroscopic or microscopic residual disease after thyroidectomy (particularly in tumors thought to be RAI nonavid and affecting the aerodigestive tract) as well as treatment of symptomatic distant metastatic foci that are RAI nonavid.

Other treatment options for local control of recurrent and/or metastatic disease exist in a limited number of centers. These include percutaneous ethanol or radiofrequency ablation for cervical nodal metastases, radiofrequency ablation of lung or bone metastases, and palliative embolization of bone metastases. In addition, there is much research activity around newer targeted systemic therapies for RAI-refractory disease (see later).

Targeted therapies. Most targeted therapies consist of TKIs. TKIs are typically reserved for patients with iodine-refractory disease because they are not curative therapy, and they can have significant side effects, including on the cardiac, renal, and hematologic systems, leading to a decrease in quality of life.[54] If available, use of genetic or molecular profiling of the tumor should be performed to identify potential therapeutic targets for a selective inhibitors against BRAF (e.g., dabrafenib), NTRK (e.g., larotrectinib, entrectinib), RET (e.g., selpercatinib, pralsetinib), or other kinases (e.g., RAS, MEK, FGFR). If no mutational targets are identified, patients are eligible for multikinase inhibitor therapy such as sorafenib, lenvatinib, cabozantinib, vandetanib, or sunitinib. These medications block several pathways responsible for tumor proliferation and survival but are considered "tumoristatic," as they eventually lose their responsiveness to tumor resistance. MKIs are typically considered for patients in whom the sum of tumor diameter is ≥2 cm and the lesions have progressed in the last 12 months or for patients suffering from DTC-related symptoms.[55] Recent interest has grown about what is known as redifferentiation therapy for RAI-refractory DTC. As more than 40% of PTCs harbor a *BRAFV600E* mutation, and this is associated with downregulated expression of the of the Na-I symporter (NIS), these tumors are often less sensitive to RAI. Some preclinical studies have shown redifferentiation of cells through inhibition of BRAF or MEK, thus promoting NIS restoration and RAI avidity. However, a recent phase III trial of the MEK1-2, RAS, and *BRAFV600E* inhibitor selumetinib did not improve the complete response rate in high-risk patients with DTC.[56]

Follow-up

After initial treatment of DTC, most patients are seen at 3- to 6-month intervals with biochemical testing and ultrasonography. ATA low-risk patients are expected to do well with low recurrence rates that would probably not be apparent for at least 3 to 5 years. Therefore, they return for follow-up in the first 6 to 12 months with serum lab testing (Tg antibody levels, thyroid function tests) and neck ultrasound. Follow-up then becomes less frequent if they demonstrate excellent response to therapy. ATA intermediate-risk patients also are followed at 6-month intervals with biochemical testing and more intensive ultrasound follow-up than ATA low-risk patients. ATA high-risk patients are evaluated every 2 to 3 months, using the same biochemical testing but with appropriate cross-sectional or functional imaging studies. Because of the more aggressive nature of their tumor, treatment response can be evaluated in the first 6 to 12 months for ATA high-risk patients, allowing timely, tailored changes to management.

The use of Tg as a marker in patients who have not undergone total thyroidectomy is an area of controversy. A recent systematic review and meta-analysis of Tg levels in patients who underwent thyroid lobectomy alone, total thyroidectomy alone, or total thyroidectomy followed by RAI revealed that the clinical utility of Tg measurement to identify recurrent or metastatic disease was low after partial thyroidectomy.[57] After total thyroidectomy, a cutoff of >1 to 2.5 ng/mL had high sensitivity for recurrent or metastatic disease.

Medullary Thyroid Cancer

MTC is an uncommon thyroid malignancy, comprising only 2% of all incident thyroid cancers in the United States.[31] Hazard and colleagues first coined the term *medullary* in 1959 to describe a unique thyroid tumor with nonfollicular characteristics and amyloid-containing stroma. Unlike DTC, MTC arises from the neuroendocrine parafollicular C cells, which secrete the polypeptide calcitonin (Fig. 73.25). MTC usually occurs as a sporadic tumor, but 25% of cases, on average, occur in the context of hereditary syndromes linked to germline mutations in the *RET* proto-oncogene, such as MEN types 2A and 2B (MEN2A and MEN2B, respectively) as well as familial MTC syndrome.

Clinical Presentation

The typical clinical presentation of MTC depends on whether the disease is sporadic or hereditary. Sporadic MTC usually presents between the fourth and sixth decades of life; the most common presentation (occurring in up to 50% of cases) is a palpable neck mass from the primary tumor itself or from associated lymphadenopathy. These tumors are usually unifocal and, based on the distribution of C cells in the thyroid, often arise in the superior lateral thyroid lobes. In patients with sporadic MTC with a palpable thyroid nodule, cervical nodal metastases are present in up to over 70% of cases and distant metastases in 10% to 15% of cases. The most common locations of distant metastasis are the liver, mediastinum, lungs, and bone.

(B) MTC exhibits cytoplasmic positivity on calcitonin staining. (Courtesy Elham Khanafshar, MD, MS, Department of Pathology and Laboratory Medicine, University of California, San Francisco.)

Hereditary MTC presents at a younger age compared with sporadic MTC; patients with familial MTC or MEN2A typically present in the third decade of life, and patients with MEN2B present before the second decade. Depending on the specific *RET* mutation, hereditary MTC can present very early in life within the first months to year (see later). Unlike in sporadic MTC, hereditary MTC often presents as multifocal disease. Fortunately, most patients with hereditary MTC are now identified at an earlier age by genetic screening of at-risk family members (see later). Hereditary MTC also can present during the diagnosis and workup of an associated disease, such as pheochromocytoma or primary hyperparathyroidism.

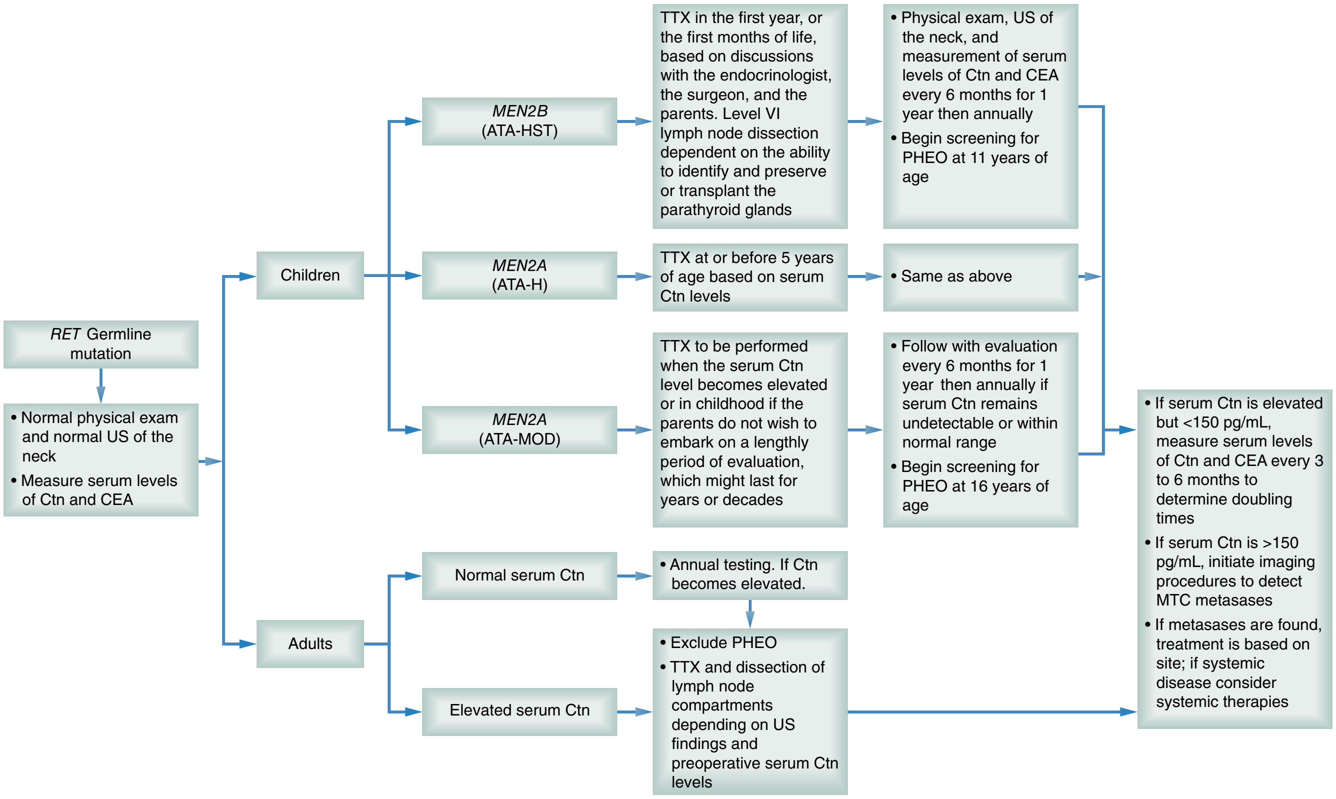
In both sporadic and hereditary MTC, elevated levels of circulating calcitonin can lead to diarrhea, flushing, and weight loss. Uncommonly, MTC also can produce a number of other hormones, such as carcinoembryonic antigen (CEA), adrenocorticotrophic hormone, chromogranin, and somatostatin, which can lead to paraneoplastic syndromes such as Cushing and carcinoid syndromes.

RET and Medullary Thyroid Cancer

The *RET* proto-oncogene is the most important gene associated with MTC. *RET* is located on chromosome 10q11.2 and encodes a transmembrane tyrosine kinase receptor with regulatory effects on cell growth and survival. Virtually all patients with a hereditary form of MTC have one of over 100 described germline mutations in *RET,* with each mutation portending a unique profile of MTC aggressiveness and frequency of other syndromic manifestations (e.g., pheochromocytoma, primary hyperparathyroidism, cutaneous lichen amyloidosis, and Hirschsprung disease). Mutations in codon C634 are the most common.

The 2015 revised ATA guidelines around the management of MTC proposed a modified risk classification system for hereditary MTC aggressiveness based mainly on the type of *RET* mutation identified in order to better inform the timing of prophylactic thyroidectomy in affected family members.[4] This classification has three risk categories: highest risk, high risk, and moderate risk. The highest-risk category includes patients with MEN2B and the codon M918T mutation in whom macroscopic MTC and nodal metastases can present within the first year of life; in these patients, total thyroidectomy is recommended as soon as possible in the first few months of life. The high-risk category comprises patients with the codon C634 and A883F mutations in whom thyroidectomy is recommended by the age of 5 years or sooner in the presence of elevated serum calcitonin levels. The moderate-risk category includes patients with all other mutations in whom either annual surveillance or thyroidectomy may be pursued. Fig. 73.26 shows the ATA management algorithm for patients with *RET* germline mutations.

RET testing in sporadic MTC is also important in two respects. First, apparently sporadic MTCs may in fact be the initial manifestation of a hereditary syndrome. Therefore, all patients



RET Germline mutation
• Normal physical exam and normal US of the neck
• Measure serum levels of Ctn and CEA
Children
Adults
MEN2B (ATA-HST)
MEN2A (ATA-H)
MEN2A (ATA-MOD)
Normal serum Ctn
Elevated serum Ctn
TTX in the first year, or the first months of life, based on discussions with the endocrinologist, the surgeon, and the parents. Level VI lymph node dissection dependent on the ability to identify and preserve or transplant the parathyroid glands
TTX at or before 5 years of age based on serum Ctn levels
TTX to be performed when the serum Ctn level becomes elevated or in childhood if the parents do not wish to embark on a lengthy period of evaluation, which might last for years or decades
• Annual testing. If Ctn becomes elevated.
• Exclude PHEO
• TTX and dissection of lymph node compartments depending on US findings and preoperative serum Ctn levels
• Physical exam, US of the neck, and measurement of serum levels of Ctn and CEA every 6 months for 1 year then annually
• Begin screening for PHEO at 11 years of age
• Same as above
• Follow with evaluation every 6 months for 1 year then annually if serum Ctn remains undetectable or within normal range
• Begin screening for PHEO at 16 years of age
• If serum Ctn is elevated but <150 pg/mL, measure serum levels of Ctn and CEA every 3 to 6 months to determine doubling times
• If serum Ctn is >150 pg/mL, initiate imaging procedures to detect MTC metastases
• If metasases are found, treatment is based on site; if systemic disease consider systemic therapies

FIGURE 73.26 Recommended management of patients at risk for hereditary medullary thyroid cancer *(MTC)* based on positive *RET* germline mutation detected on genetic screening. *ATA-MOD,* American Thyroid Association Moderate Risk; *ATA-H,* American Thyroid Association High Risk; *ATA-HST,* American Thyroid Association Highest Risk; *CEA,* carcinoembryonic antigen; *Ctn,* calcitonin; *MEN2,* multiple endocrine neoplasia type 2; *PHEO,* pheochromocytoma; *TTX,* total thyroidectomy. (From Wells SA Jr, Asa SL, Dralle H, et al. Revised American Thyroid Association guidelines for the management of medullary thyroid carcinoma. *Thyroid.* 2015;25:567-610.)

with a diagnosis of MTC or C-cell hyperplasia should undergo genetic testing to rule out hereditary disease. Second, approximately 50% of sporadic MTCs have somatic *RET* mutations, which are associated with a higher incidence of nodal metastases, persistent disease, and disease-specific mortality. Therefore, they warrant more aggressive surveillance and treatment.

Workup

MTC can be definitively diagnosed by FNA biopsy, from which cytology can demonstrate the presence of stromal amyloid and absence of thyroid follicular cells. Measurement of elevated calcitonin levels in the FNA washout fluid increases the accuracy of FNA to 98%. Once MTC is diagnosed, measurement of serum calcitonin and CEA is recommended to establish a pretreatment baseline. Measurement of serum calcitonin and CEA as a screening test in the absence of cytologically confirmed MTC, on the other hand, is controversial. ATA guidelines recommend that a serum calcitonin of at least 100 pg/mL should be considered suspicious for MTC. In addition, a calcitonin value of at least 500 pg/mL before treatment should raise the suspicion for distant metastases. Notably, serum calcitonin can be elevated because of multiple states other than MTC, including autoimmune thyroiditis, hyperparathyroidism, lung cancer, and age <3 years. Serum CEA is not a specific biomarker for MTC and thus is more useful as an adjunctive test. CEA is often elevated in more aggressive MTCs that have lost calcitonin secretory function, thus acting as a marker for dedifferentiation. Measurement of both serum calcitonin and CEA is recommended to establish a pretreatment baseline and to track disease progression.

Neck ultrasound is the most important preoperative imaging study in MTC in that it provides sensitive characterization of thyroid lesions and cervical lymph nodes. Cross-sectional imaging of the neck and chest (preferably CT with IV contrast) may be indicated depending on the suspicion for bulky or locally advanced disease. In higher-risk patients such as those with high-burden cervical disease, symptoms suspicious for distant metastases, or serum calcitonin levels ≥500 pg/mL, radiographic survey for distant metastases should be performed. The most common tests include multiphase CT or MRI of the liver, axial MRI, and bone scintigraphy.

All patients with hereditary MTC should be biochemically screened for pheochromocytoma and primary hyperparathyroidism. If a pheochromocytoma is identified, treatment for the pheochromocytoma should precede that of MTC in virtually all cases. Primary hyperparathyroidism can be surgically managed at the time of thyroidectomy for MTC if present concurrently.

Surgical Treatment

The surgical treatment for MTC is divided into that for clinically evident disease versus that performed as a prophylactic measure at an early age in hereditary MTC syndromes.

Clinically evident MTC is treated with, at a minimum, total thyroidectomy and bilateral central neck dissection, as central nodal metastases are present in more than 70% of cases with palpable tumors regardless of tumor size. The role of routine lateral neck dissection (levels II–V) is controversial. One school of thought advocates for prophylactic lateral neck dissection on at least the side ipsilateral to the primary tumor because several single-institution series have demonstrated a >70% incidence of ipsilateral lateral neck metastases as well as a >40% incidence of metastases in the contralateral lateral neck. The opposing opinion cites the morbidity of lateral neck dissection, along with the fact that over 65% of patients with MTC have evidence of systemic disease even after bilateral central and lateral neck dissections. Recognizing this controversy, the current ATA guidelines recommend that prophylactic ipsilateral and contralateral lateral neck dissection be considered based on serum calcitonin levels; for example, in patients with ipsilateral lateral neck metastases noted on preoperative ultrasound, prophylactic contralateral lateral neck dissection should be considered if the basal serum calcitonin level is at least 200 pg/mL.

For at-risk children with hereditary MTC syndromes, prophylactic total thyroidectomy is recommended. The progression of hereditary MTC generally proceeds sequentially from C-cell hyperplasia, to MTC, to locoregional lymph nodes, and ultimately to distant metastases. The purpose of prophylactic thyroidectomy is to remove the thyroid before MTC develops; or if cancer has developed, it is confined to the thyroid, such that central neck dissection is unnecessary and cure is secured. As described earlier, the optimal timing for prophylactic thyroidectomy depends largely on the specific germline *RET* mutation, which can predict typical age of MTC onset as well as aggressiveness of disease. This must be balanced with the risk of surgical complications in children and infants, which are elevated compared with adolescents and adults even in the hands of experienced surgeons.[58]

Management of the parathyroid glands during thyroidectomy in patients with MEN2A is unique because of the 20% penetrance of primary hyperparathyroidism. As mentioned earlier, screening for primary hyperparathyroidism should be done before thyroidectomy. For biochemically diagnosed primary hyperparathyroidism, a four-gland exploration should be performed at the time of thyroidectomy, with intentional resection performed only for enlarged glands. Most cases of primary hyperparathyroidism in MEN2 involve a single parathyroid adenoma. If a normal parathyroid gland is devascularized during surgery, it should be autotransplanted into a heterotopic site (e.g., the nondominant forearm) for ease of access because of the risk of primary hyperparathyroidism developing in the transplanted tissue later in life.

For patients with familial MTC, MEN2B, or sporadic MTC undergoing thyroidectomy, devascularized parathyroids may be autotransplanted into the sternocleidomastoid because these patients are not at increased risk for primary hyperparathyroidism.

Postoperative Surveillance and Prognosis

MTC is associated with an overall 50% rate of disease recurrence; therefore, close postoperative monitoring should begin as soon as 3 months after surgery with a check of serum calcitonin and CEA levels. If these values are negative or in the normal range, they should be repeated at 6-month intervals for the first year and then annually thereafter. The doubling time of calcitonin (and to a lesser extent CEA) is an accurate estimate of MTC growth as well as a prognostic indicator. A calcitonin doubling time of less than 6 months is associated with a 5-year survival rate of 25%, compared with 92% if the doubling time is ≥6 months.[59] Elevated calcitonin levels raise the suspicion of recurrence and should be further evaluated with physical examination and neck ultrasound; significantly elevated calcitonin levels (>150 pg/mL) should prompt additional imaging workup for recurrent or persistent distant disease, including chest CT, multiphase CT or MRI of the liver, bone scintigraphy, and MRI of the pelvis and axial skeleton.

TABLE 73.5 Summary of the AJCC 8th Edition Staging System for MTC

TNM STAGE GROUPING	AJCC STAGE
T1, N0, M0	I
T2/3, N0, M0	II
T1/2/3, N1a, M0	III
T4a, Any N, M0	IVA

AJCC, American Joint Committee on Cancer; *MTC,* medullary thyroid carcinoma; *TNM,* tumor-node-metastasis.

Data from Amin MB, Edge SB, Greene FI, et al. *AJCC Cancer Staging Manual*. 8th ed. New York: Springer; 2018.

Staging of MTC is summarized in Table 73.5. Although the definitions for the T, N, and M categories are the same as for DTC, the prognostic stage groupings are different. The overall 10-year survival of patients with MTC is approximately 80%. Disease confined to the thyroid gland at presentation confers an excellent long-term prognosis with 5-year overall survival approaching 95%. The presence of cervical nodal metastases is associated with a reduction in survival to approximately 75%, and distant metastases are associated with compromised survival further to 35%.

Despite its widespread use, the current AJCC TNM staging system has been modeled largely after that used for DTC. However, MTC is inherently distinct from DTC, so the generalizability of one staging system to another is likely not appropriate. Adam and colleagues proposed a revision in the staging groups based on a recursive partitioning analysis using the National Cancer Database and the Surveillance, Epidemiology, and End Results (SEER) databases to better divide MTC patients into four groups with more similar overall survival.[60] The proposed revision led to a more useful and stepwise downward progression of survival estimates compared with the existing TNM system, with 5-year overall survival of 92% to 94%, 86% to 87%, 69% to 81%, and 33% to 35% for stages I, II, III, and IV disease, respectively.

Targeted therapy. The *RET* mutations that underlie many cases of MTC have been found to be an effective therapeutic target. *RET*-targeting TKIs have emerged as an effective targeted therapy, although resistance can occur. Currently, optimal timing for initiation of TKI in MTC is unclear, and ATA guidelines recommend initiating TKI therapy for patients with radiographic evidence of disease progression or symptomatic disease.[4]

TKIs for MTC can be multitargeted or *RET*-specific. Vandetanib and cabozantinib are two multitarget TKIs that have been approved by the US Food and Drug Administration (FDA). Both drugs demonstrated significantly longer progression-free survival for patients with locally advanced or metastatic MTC who received the treatment drug compared with placebo. Other multitarget TKIs that have been investigated in the treatment of MTC include sunitinib, sorafenib, lenvatinib, and anlotinib. More recently, the US FDA approved selpercatinib and pralsetinib for

RET-altered MTC because these TKIs are more *RET*-specific and have an improved side effect profile. However, patients can develop resistance to these newer TKIs as well. Future strategies in the treatment of MTC will need to address optimal timing of TKI therapy and ways to overcome resistance mutations.

Anaplastic Thyroid Cancer

ATC is an extremely aggressive undifferentiated tumor of follicular cell origin. ATC is uncommon, comprising approximately 1% of all thyroid cancers.[31] The mean age at diagnosis is 65 years, with a 2:1 female-to-male incidence ratio; a history of multinodular goiter and/or previous thyroidectomy exists in up to 50% of patients. ATC is thought to arise from DTC of follicular cell origin (particularly PTC), based on the coexistence of PTC in at least 30% of cases as well as longitudinal case studies demonstrating dedifferentiation and transformation from DTC to ATC over time. On a molecular level, the dedifferentiation event in ATC may involve mutations in the *TP53* and *PIK3CA* genes or genes in the catenin family.

Patients with ATC typically present with a rapidly enlarging neck mass. Unlike in other thyroid tumors, local cervical symptoms are frequent and severe and include neck pain, dyspnea, cough/hemoptysis, dysphagia, and hoarseness. Over half of patients have cervical lymphadenopathy, and 15% to 50% of patients have distant metastases at the time of presentation. The most common sites of distant metastases include the lungs, bone, and brain; other sites may include the skin, liver, kidneys, pancreas, heart, and adrenal glands.

Diagnosis and Staging

Because of its rapidity in growth and spread, timely diagnosis is of the essence when ATC is suspected. Diagnosis can be confirmed with FNA (~60% cases), but this can often be challenging because of the lack of cell differentiation. When FNA is not diagnostic, core biopsy is typically helpful, particularly with ultrasound guidance to identify particular solid areas or those of most concern; incisional biopsy is typically not required.[61] Cytologic features of ATC include mixed patterns of spindled, pleomorphic giant, and squamoid cells with mitotic figures, atypical mitoses, and extensive necrosis. ATCs typically do not secrete or stain for Tg, although differentiated components of tumors may retain the ability to make Tg (Fig. 73.27). Staging for ATC should proceed expeditiously because of the rapid progression of disease. Imaging includes neck ultrasound and cross-sectional imaging of the neck and mediastinum to assess the extent of locoregional disease. Unlike in DTCs or MTCs, PET scan is recommended for a metastatic survey in the initial evaluation of ATC because of its intense PET avidity. Management of ATC should follow the 2021 ATA guidelines, which highlight the increasing role of molecular targeted therapies for patients with ATC.[61]

According to the AJCC TNM system, all ATCs are considered stage IV disease because it is the most lethal type of thyroid cancer, with 1-year overall survival of 20%. Prompt staging and multidisciplinary management are essential because of the associated high mortality. [^{18}F]-FDG PET/CT of the whole body is preferred for staging ATC because it can identify metastases that may not be detected on CT alone. However, if PET/CT is not available, IV contrast-enhanced CT of the neck, chest, abdomen, and pelvis can be obtained. Although brain metastases are uncommon at presentation, they are associated with worse prognosis. Therefore, the ATA has recommended brain MRI as part of the initial staging algorithm for ATC when clinically indicated.

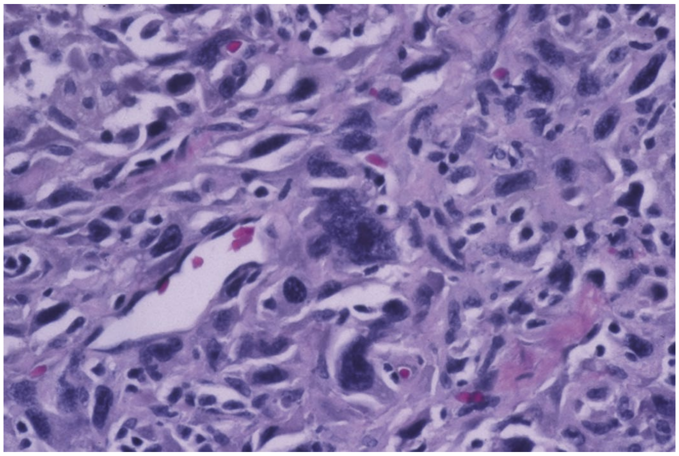

FIGURE 73.27 Anaplastic thyroid cancer. Hematoxylin and eosin staining showing marked nuclear pleomorphism, oval to spindle-shaped cells, and multinucleated tumor cell. (From Baloch ZW, Livolsi VA. Surgical pathology of the thyroid gland. In: Randolph GW, ed. *Surgery of the Thyroid and Parathyroid Glands 2*. Philadelphia: Elsevier Saunders; 2013:420.)

Surgical Management

Once diagnosis and staging of ATC are completed, resectability of the primary tumor should be evaluated. Patients with disease limited to the neck may be candidates for resection. Surgery should aim to achieve an R0 or R1 resection, which has been associated with longer survival. Extent of surgery typically involves total thyroidectomy with lymph node dissection. More radical resection to involve major vascular structures, esophagus, trachea, or larynx is generally not recommended because of the poor prognosis of ATC and should be discussed within a multidisciplinary team with consideration of molecular testing. Although a tracheostomy may be felt to be necessary as part of the initial surgery, especially depending on the extent of bilateral neck dissection, many patients with ATC do not require tracheostomy unless they endorse stridor or acute airway distress.

Adjuvant Therapy

Studies have demonstrated that survival and local disease control are optimized with R0/R1 resection, followed by radiotherapy and chemotherapy. Radiotherapy should aim to begin within 6 weeks after surgery. The 2021 ATA guidelines recommend cytotoxic chemotherapy involving a taxane, with or without anthracyclines or platin, in patients with ATC who receive definitive-intention radiation.

Targeted systemic therapies are increasingly being applied in ATC, especially for patients with advanced or initially unresectable disease. *BRAF*^{V600E} is the most common targetable mutation in ATC, and in 2018, dabrafenib/trametinib (*BRAF*/*MEK* inhibitor combination) was approved by the US FDA for use in *BRAF*^{V600E}-mutated ATC. *BRAF*-directed therapy can produce prompt tumor regression, and it is recommended for use in patients with distant metastases from *BRAF*^{V600E}-mutated ATC. Neoadjuvant use of *BRAF/MEK* inhibition has been explored to render an unresectable primary tumor resectable. Emerging data suggest that neoadjuvant *BRAF* inhibitory therapy followed by surgical resection can potentially lead to prolonged survival.

HISTORY OF THYROID SURGERY

The history of thyroid surgery began more than 1000 years ago.[62] Most records agree that the first thyroidectomy was performed for endemic goiter by the legendary surgeon Abu al-Qasim in 952 AD, although the patient was said to have barely survived because of torrential blood loss during the procedure. The majority of the ensuing millennium did not see encouraging advancements in either the understanding of the thyroid gland's function or its safe extirpation. In the 12th century, Roger Frugardii of the Italian Salerno school described a morbid method of thyroid removal involving the insertion of hot iron setons through the skin and into the gland, with gradual superficialization of the gland until the seton and thyroid tissue penetrated through the skin and were removed. This type of procedure exemplified what the early Catholic Church deemed to be the brutality and uncouthness of surgery, which led to a retreat of surgery from the mainstream of medicine and science during much of medieval European history.

The anatomy of the thyroid was first described in the early 16th century by Leonardo da Vinci; unfortunately, he did not understand the thyroid gland's function beyond its filling in an empty space in the neck between muscle layers in order to protect the trachea from the sternum. As the study of anatomy and surgery became more culturally acceptable during the Renaissance, additional incremental advancements in the understanding of thyroid anatomy occurred. The term *thyroid* was first coined by the anatomist Thomas Wharton in 1646; it was a derivation of the Greek word *thyreos,* or "shield."

Advancements in thyroid surgery were relatively few and far between until well into the 19th century. Wilhelm Fabricius described a case in the mid-1600s of a "rash" and "audacious doctor" who performed the first thyroidectomy using scalpels for a goiter in a 10-year-old female patient who died on the operating table; this surgeon was reported to have been imprisoned as a result. The first well-documented successful partial thyroidectomy was performed in 1791 by Pierre Joseph Desault during the French Revolution, and other surgeons reported small case series of successful thyroidectomies over the ensuing 50 years. Notable among them was the German surgeon Johann Hedenus, whose 0% mortality rate after the removal of six "suffocating" goiters was considered remarkable for the time. Despite this, thyroid surgery was still associated with (at a minimum) a 40% mortality rate in the early to mid-1800s, such that the leading surgical figures and professional associations of the time emphatically advised against performing thyroidectomy. Thyroid surgery was deemed by Liston "a proceeding by no means to be thought of," by Diffenbach as "most thankless, most perilous…foolhardy performances," and by Gross as "…horrid butchery. No honest and sensible surgeon would ever engage in it." The French Academy of Medicine frankly banned thyroid surgery during this time.

Starting in the mid-19th century and continuing on into the early 20th century, the course of thyroid surgery rapidly evolved from a dangerous and morbid endeavor into a safe, elegant, and modern practice. The practice of surgery as a whole advanced because of the triple developments of anesthesia, antisepsis/infection prophylaxis, and instrumentation for hemostasis. Thanks in large part to these innovations, the surgical giants of the day were able to more carefully study and refine surgical thyroidology. Theodor Billroth's foray into thyroid surgery was initially marked by 16 deaths among 36 thyroidectomies; however, he was able to dramatically reduce his mortality rate to 8% after introducing newer methods of hemostasis and antisepsis in his surgical practice. Theodor Kocher, Billroth's pupil, is widely regarded as the "father of modern thyroid surgery." He performed more than 5000 thyroidectomies during his career, with an associated mortality rate of 0.5%, which was widely attributed to his extreme meticulousness in antisepsis and hemostatic techniques. His remarkable surgical results as well as his seminal research contributions to the understanding of thyroid function led to his receiving the Nobel Prize in Medicine and Physiology in 1909, the first Nobel ever awarded to a surgeon. The Australian surgeon Thomas Dunhill is credited for his excellent results pioneering a safe bilateral operation of unilateral complete thyroid lobectomy with contralateral subtotal thyroid lobe resection for thyrotoxicosis, an operation that still bears his name today.

William Stewart Halsted's stature as the "father of modern surgery" and creator of the contemporary American surgical residency program makes it sometimes easy to overlook his many contributions to thyroid surgery. His research elucidated parathyroid blood supply as well as "ultraligation" of the distal thyroid artery branches to avoid parathyroid gland devascularization and avoid postoperative tetany. He also performed experiments that supported the mechanistic connection between hypoparathyroidism and tetany and its reversal with either calcium supplementation or parathyroid transplantation. Halsted further improved upon the techniques he learned from Billroth and Kocher by improving surgical instrumentation for hemostasis and introducing surgical gloves for sterile technique. Two of his trainees, George Crile and Frank Lahey, went on to become luminaries in thyroid surgery. Ultimately, Halsted wrote that thyroid surgery "typifies perhaps better than any other operation the supreme triumph of the surgeon's art."

Charles Mayo and his medical colleague Henry Plummer demonstrated the safe conduct of thyroidectomy for Graves disease with preoperative iodine preparation. Mayo's surgical volume and superlative outcomes far exceeded other contemporaries and led to his reputation for being the "father of American thyroid surgery."

Additional innovations over the past century have undoubtedly improved the conduct of modern thyroid surgery, but the influence around the turn of the 20th century of the previously mentioned luminaries, and particularly Kocher, remain unmatched.

THYROIDECTOMY

Indications and Nomenclature

Broadly speaking, the indications for thyroidectomy include the following:

1. Hyperthyroidism for which nonsurgical management has failed or is not preferred
2. Goiters with or without local compressive symptoms
3. Thyroid nodules and thyroid cancer

The extent of thyroid resection was a topic of much discussion historically, but in modern practice, the vast majority of thyroid resections fall under two categories: *total thyroidectomy,* in which all or nearly all of the visible thyroid gland is excised, and *thyroid lobectomy* (also referred to as *hemithyroidectomy*), in which all of the visible thyroid on one side is excised along with the isthmus and, if present, the pyramidal lobe. *Near-total thyroidectomy,* in which less than 1 g of remnant thyroid tissue is left at the ligament of Berry, is also commonly performed. *Subtotal thyroidectomy,* in which 3 to 5 g of thyroid tissue is left, is less commonly performed today. The rationale for these lesser-extent lobar resections has been to protect the RLN and blood supply to the parathyroids as well as to preserve thyroid function without the need for thyroid hormone replacement. Lastly, *isthmusectomy* is resection of only the thyroid isthmus and pyramidal lobe.

Thyroidectomy Outcomes

There are over 130,000 thyroidectomies performed annually in the United States, making thyroidectomy one of the most common surgical procedures. The rate of thyroidectomy was noted to increase in pace with the increased number of thyroid biopsies and diagnoses of thyroid cancer.[63] Deescalation of therapy for DTC has led to substantial reduction in the use of postthyroidectomy RAI and a slight increase in thyroid lobectomy compared with total thyroidectomy from 2000–18, although this is projected to continue to increase over time.[33] Thyroidectomy has evolved from a dangerous and morbid operation historically (see earlier) to a generally safe procedure, most of which likely can be performed safely in the outpatient setting.

Despite its safety, thyroidectomy is associated with a risk of complications such as RLN and EBSLN injury, hypoparathyroidism, and neck hematoma (see later), which, although rare, can nevertheless lead to significant patient morbidity and disability when they occur. Various efforts to minimize these complications and optimize thyroidectomy outcomes exist. One approach is to standardize the teaching and performance of thyroidectomy technique, such as that found in the *Operative Standards for Cancer Surgery* initiative by the American College of Surgeons, in an effort to minimize the potentially harmful effects of significant deviations of technique from evidence-based norms.[64]

Other efforts to study and improve thyroidectomy have focused on concentrating expertise and referral patterns into more experienced hands because surgeon experience measured by operative volume has been clearly established as an important and modifiable determinant of thyroidectomy outcomes. A large body of literature has demonstrated that higher-volume surgeons on average have fewer complications, shorter hospital stays, and lower costs. The threshold for what qualifies as a “high-volume” surgeon has been studied extensively; a recent study of 16,954 patients undergoing total thyroidectomy between 1998 and 2009 in the Nationwide Inpatient Sample database demonstrated on restricted cubic splines analysis that patient outcomes improved with increasing surgeon volume up to a threshold of 26 cases per year.[65] Data such as these will be important for setting minimum case volume thresholds for professional society credentialing and volume-based referral initiatives.

Preoperative Preparation

All patients undergoing thyroidectomy should have biochemical assessment of thyroid function as well as appropriate imaging studies, particularly neck ultrasound. As described in more detail earlier, thyroid nodular disease or malignancy should be assessed with FNA biopsy as indicated. For operations performed for hyperthyroidism, patients should ideally be rendered euthyroid by the time of operation with antithyroid medication with or without β-blockade, although the operation sometimes can be safely performed in a hyperthyroid state. For Graves disease, Lugol solution or SSKI also can be administered within 10 days of surgery per surgeon preference for rapid correction of thyroid function. Measurement of serum calcium levels should be performed in patients at risk for concurrent primary hyperparathyroidism, such as those with MEN2A.

Assessment of Voice and Laryngeal Function

Voice assessment is critical before thyroidectomy because vocal cord dysfunction is one of the most important complications of thyroid surgery. Vocal cord dysfunction can lead to significant decrement in quality of life, and it is one of the most frequent causes of medicolegal action. All preoperative voice assessments include a thorough patient history around voice changes and abnormalities, prior history of surgery that may have been associated with the risk of injury to the vagus verve or the RLN, and the surgeon’s assessment of the voice.

Laryngoscopy is an indispensable tool in the objective preoperative assessment of vocal cord function and must be performed in patients at higher risk for vocal cord paralysis, including those with a history of voice changes or prior relevant surgical history or thyroid cancers with fixed masses, posteriorly extending extrathyroidal extension, or bulky metastases. The role of routine preoperative laryngoscopy for all patients regardless of risk assessment is controversial. Proponents of routine laryngoscopy in all patients cite (1) its ability to confirm preoperative vocal cord dysfunction in up to 3.5% of patients with benign thyroid disease and in up to 8% of patients with thyroid cancer; (2) its ability to definitively diagnose preoperative dysfunction is important for operative management in these cases, and (3) vocal cord paralysis can be associated with a normal voice in up to 20% of cases.[66] On the other hand, proponents of selective laryngoscopy state that the true incidence of preoperative vocal cord dysfunction in patients with a truly negative risk assessment by history and physical examination is closer to 0.5% and that subjecting all thyroid surgery patients to laryngoscopy is not cost-effective.[67]

Transcutaneous laryngeal ultrasound has emerged as a noninvasive alternative to laryngoscopy for assessment of vocal cord function in selected patients undergoing thyroidectomy. Studies in both Asian and Western patients have demonstrated high accuracy of laryngeal ultrasound for the detection of vocal cord paralysis (sensitivity and specificity 93%–100% and 97%–100%, respectively) as well as broad applicability in thyroid surgery practices, with over 74% of examinations able to adequately visualize the vocal cords for assessment.[68] In addition to its noninvasiveness, other advantages of this modality include its low cost, rapid learning curve, and increased efficiency if performed as part of another ultrasound examination. It is less reliable in older and male patients largely because of inability of the transducer to penetrate beyond thyroid cartilage calcification.

Current American Association for Endocrine Surgeons (AAES) guidelines for thyroid surgery recommend that all patients undergoing thyroid surgery have noninvasive preoperative voice assessment as a part of the physical examination, with the selective use of laryngoscopy for patients with preoperative voice abnormalities, history of cervical or upper chest surgery, or known thyroid cancer with posterior extrathyroidal extension or extensive nodal metastases.[69] Laryngeal ultrasound is mentioned as a potentially useful adjunct in the AAES guidelines.

Technique

Anesthesia and Positioning

Most thyroidectomies are performed under general endotracheal anesthesia. A neuromonitoring-specific endotracheal tube with contact electrodes for the vocal cords can be used if intraoperative neuromonitoring (IONM) is planned (see later). The patient is placed supine with both arms tucked. The back is raised 20 degrees, and the neck is extended by placing a soft roll behind the scapulae, with the head resting on a foam or gel ring; this brings the thyroid up to a more anterior and superior position in the neck, which is particularly helpful for glands that have substernal extension. The head is well supported to prevent neck hyperextension and postoperative posterior neck pain.

Intraoperative preincision neck ultrasound can be useful for confirming the findings of preoperative imaging and identifying any possible new findings as well as for assessing the overall anatomy of the thyroid to facilitate incision placement and operative planning.

Incision and Initial Exposure of the Thyroid

A centrally placed transverse incision is made between the sternal notch and the cricoid cartilage, with effort made to place the incision in a normal skin line of the neck for cosmetic purposes (Fig. 73.28). The length of the incision is typically 4 to 5 cm but should be sized based on the volume of the gland being excised as well as patient factors, such as body habitus and degree of neck extension. The incision is extended through the platysma muscle, and subplatysmal flaps are raised up to the thyroid cartilage superiorly and down to the sternal notch inferiorly. Care is taken to identify the anterior jugular veins draped between platysma and the strap muscles.

The strap muscles are separated in the midline via an incision through the superficial layer of the deep cervical fascia starting at the sternal notch and extending cephalad to the thyroid cartilage. For a cancer operation, dissection of the thyroid gland is generally begun on the side of the suspected tumor. The sternohyoid, which is the more superficial of the strap muscles, is separated from the deeper sternothyroid muscle by blunt dissection. This dissection can be taken as far laterally until the ansa cervicalis is visible at the lateral border of the sternothyroid; this maneuver is useful for thyroid mobilization, particularly for larger goiters. The sternothyroid is then dissected off of the underlying thyroid capsule, and with the thyroid steadily retracted and rotated anteromedially, the carotid sheath is identified laterally (Fig. 73.29). For mobilization of larger glands, the sternothyroid may be partially or completely divided near its superior attachment to the thyroid cartilage, to be reapproximated during closure. The middle thyroid vein is identified laterally and ligated and divided.

Dissection and Release of the Superior Pole

The superior pole attachments are separated from the surrounding muscles and exposed mostly in a blunt fashion with a small peanut sponge or other dissector. These exposure maneuvers are carried out superolaterally and posteriorly, with downward and lateral countertraction of the thyroid using large Kelly or Allis

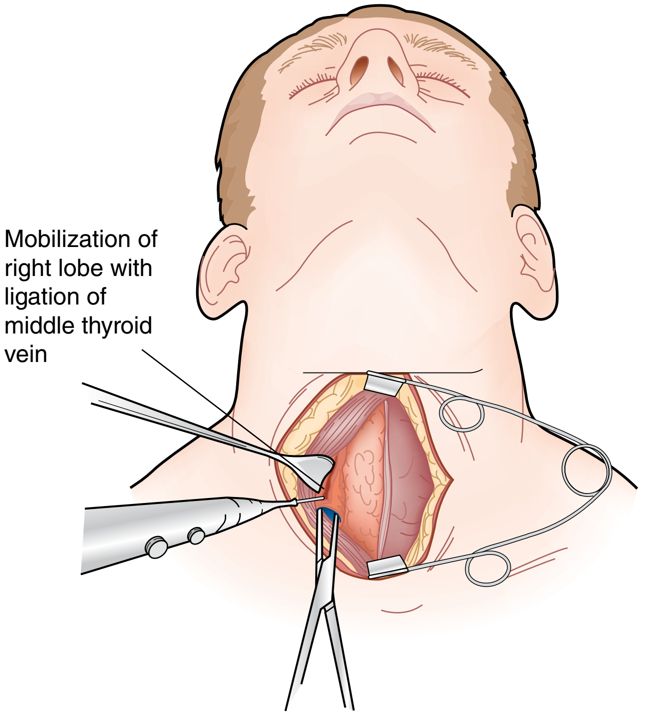

FIGURE 73.28 Image depicting a cervicotomy incision to facilitate exposure. After creation of a subplatysmal plane, the strap muscles (sternohyoid and sternothyroid) are separated by dividing the tissues in the avascular midline plane from the thyroid cartilage to the suprasternal notch. The thyroid lobe is exposed by mobilizing the strap muscles away from the lobe by means of lateral retraction on the muscles. The middle vein is exposed, divided, and ligated. (From Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia: Saunders; 1995.)

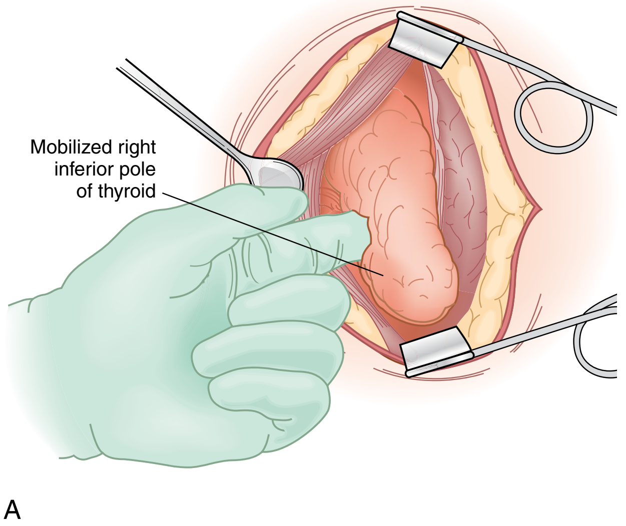

Mobilization of thyroid near inferior thyroid artery and recurrent laryngeal nerve

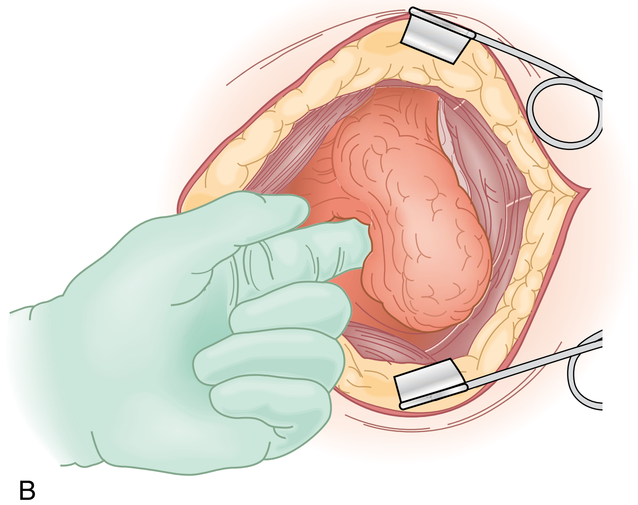

FIGURE 73.29 (A–B) The thyroid lobe is retracted medially to allow the posterolateral surface of the thyroid to be exposed. (From Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia: Saunders; 1995.)

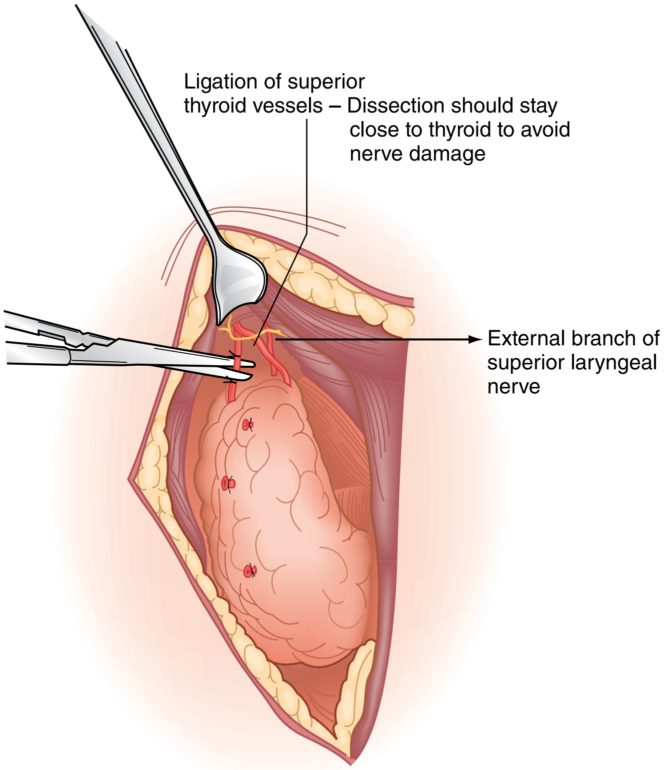

Ligation of superior thyroid vessels – Dissection should stay close to thyroid to avoid nerve damage
External branch of superior laryngeal nerve

FIGURE 73.30 Downward and lateral traction exposes the superior-pole vessels, including branches of the superior thyroid artery. The external branch of the superior laryngeal nerve courses along the cricothyroid muscle just medial to the superior pole vessels. To avoid injury to this nerve, the superior-pole vessels are divided individually as close as possible to the point where they enter the thyroid gland. (From Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia: Saunders; 1995.)

clamps (Fig. 73.30). This exposes the superior-pole thyroid vessels as well as some connective tissue lateral to the superior pole. These lateral tissues are carefully mobilized to below the level of the cricothyroid muscle, as the RLN passes through the Berry ligament and dives deep into the laryngeal insertion point at the level of the cricoid cartilage.

The superior pole is similarly separated from the cricothyroid muscle medially with gentle blunt dissection. There is an avascular space between the medial superior pole and the cricothyroid muscle, often referred to as the *space of Reeves,* which is helpful for progressive dissection of the superior pole vessels. These vessels are individually isolated, ligated, and divided; the use of energy-sealing devices may replace or augment manual ligation. Care must be taken to divide these vessels close to the surface of the thyroid in order to prevent injury to the EBSLN; neuromonitoring can also assist in its identification and preservation (see later). Division and release of the superior pole vessels allow for easy sweeping of the remaining filmy tissues away from the posterior aspect of the superior pole via blunt dissection. At this point in the dissection, the superior parathyroid gland is often identified behind the mid-superior pole at the approximate level of the cricoid cartilage.

Mobilization of Inferior Pole and Medial Rotation of the Thyroid Lobe

The mobilization of the lateral and inferior aspects of the thyroid lobe includes identification of the inferior parathyroid gland. With the inferior thyroid lobe grasped with an Allis or large Kelly clamp and retracted anteromedially, the inferior pole vessels entering anterolateral to the tracheal surface are ligated and divided. Retraction of the strap muscles exposes the carotid artery laterally, and the thyroid is progressively rotated and delivered from the wound in an anteromedial direction. The lymphoadipose tissues immediately adjacent to the lateral aspect of the thyroid are dissected off with a combination of sharp dissection with fine-tipped dissectors and ligation of small vessels as well as blunt sweeping with the peanut sponge.

The inferior parathyroid is usually encountered during these maneuvers as the posterolateral thyroid is exposed. The location of the inferior parathyroid gland is less constant than that of the superior gland, but it is invariably located on a plane anterior to the RLN and inferior to the inferior thyroid artery as this blood vessel crosses the RLN. In its typical location, the inferior gland is often adherent to the posterolateral surface of the inferior thyroid lobe. All normal parathyroid glands should be carefully dissected and swept away from the thyroid on as broad a vascular pedicle as possible in order to prevent devascularization.

Identification of the Recurrent Laryngeal Nerve and Completion of Lobectomy

Once the superior and inferior attachments of the thyroid lobe are freed, the majority of the gland aside from its tracheal attachments can be delivered from the incision with anteromedial rotation and retraction. Judicious retraction is performed with either a peanut sponge or with a finger wrapped with gauze. Care must be taken not to use excessive force when retracting the thyroid at this point because this may stretch the RLN at its tethering points at the Berry ligament and the larynx, which can increase the risk of neuropraxic injury.

The course of the right and left RLN varies considerably. The left RLN is typically situated deeper and more medially and runs in a straighter cephalocaudal direction along the tracheoesophageal groove, whereas the right RLN takes a more superficial and oblique course and may pass either anteriorly or posteriorly to the inferior thyroid artery (Fig. 73.31). Two commonly used rules of thumb for RLN identification are (1) it is located within 1 cm anteromedial to the superior parathyroid gland, at the level where the nerve crosses the inferior thyroid artery, and (2) its course through the ligament of Berry is also situated just underneath and medial to the tubercle of Zuckerkandl, the small posterior protuberance of the midthyroid lobe. Utmost care must be taken not to transect any substantial structures or tissues in this area until the RLN, inferior thyroid artery, and blood supply to the parathyroid glands are dissected and confidently identified (Fig. 73.32).

Once the parathyroids and RLN are identified and preserved, the remainder of the thyroid may be dissected in a more superficial plane off of the trachea, including the ligament of Berry. The course of the RLN here can vary such that it travels just under, within, or even anterior to the ligament of Berry; this requires careful mobilization of the nerve while the thyroid is peeled off this area (Fig. 73.33). Fine dissection of tissues with the judicious use of manual pressure, small clips, ties, and bipolar forceps is encouraged because this area contains tiny vessels that can nevertheless bleed and obscure the operative field. Occasionally, it may be appropriate to leave a tiny amount of thyroid tissue in the interest of protecting the nerve. The rest of the attachments to the anterior trachea are then

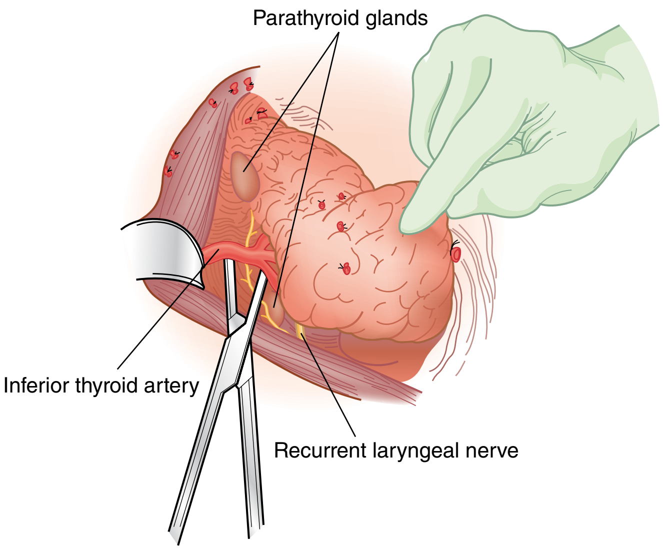

FIGURE 73.31 As the thyroid is retracted medially, gentle dissection is used to expose the parathyroid glands, inferior thyroid artery, and recurrent laryngeal nerve (RLN). The RLN usually passes deep to the inferior thyroid artery but may lie anterior to it. It is best found by careful dissection just inferior to the artery. The nerve can then be traced upward, and its position in relation to the thyroid can be determined. Parathyroid glands that lie on the thyroid surface can be mobilized with their vascular supply and preserved. (From Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia: Saunders; 1995.)

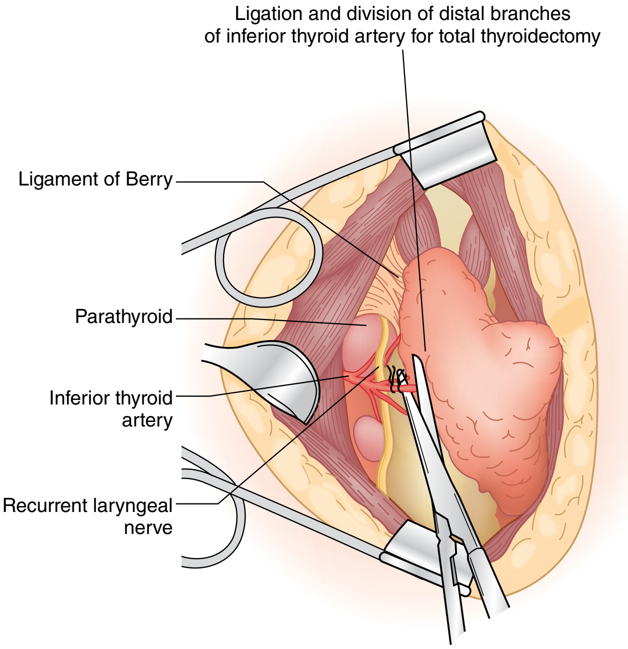

Ligation and division of distal branches of inferior thyroid artery for total thyroidectomy
Ligament of Berry
Parathyroid
Inferior thyroid artery
Recurrent laryngeal nerve

FIGURE 73.32 To complete the lobectomy, branches of the inferior thyroid artery are divided at the surface of the thyroid gland. The inferior thyroid veins can then be ligated and divided. Superiorly, the connective tissue (ligament of Berry), which binds the thyroid to the tracheal rings, is carefully divided. Several small accompanying vessels are usually present, and the RLN is closest to the thyroid and most vulnerable at this point. Division of the ligament allows the thyroid to be mobilized medially. (From Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia: Saunders; 1995.)

divided, and the entire thyroid lobe should now be completely mobilized and freed (Fig. 73.34).

If a unilateral lobectomy is planned, the isthmus is divided lateral to the midline in order to minimize the risk of subsequent hypertrophy of the remaining gland (alternatively, the isthmus also can be divided early on before dissection of the lobe per the surgeon's preference to facilitate mobilization). The gland can be divided either with an energy sealing device or clamped and oversewn depending on the surgeon's preference (Fig. 73.35). The pyramidal lobe, present in up to 80% of patients, drapes cephalad from the isthmus just to the right or (more commonly) left of midline and may extend as high as the hyoid bone. This must be dissected until thyroid tissue tapers into a fibrous band before division and ligation.

The specimen is properly oriented with sutures and checked to ensure that no parathyroid tissue was inadvertently removed before passing it off for pathologic examination.

Closure

Meticulous hemostasis is necessary before closure in order to minimize the risk of postoperative neck hematoma (see later). Some surgeons use a Valsalva maneuver performed by anesthesia as a confirmation of hemostasis under increased intrathoracic and cervical pressure. For closure, the sternothyroid and sternohyoid muscles are reapproximated with 3-0 absorbable sutures, with a small opening left in the lower midline to facilitate any blood to exit the deeper resection bed and into the superficial spaces. The platysma is reapproximated with similar sutures, and the skin is closed with a fine subcuticular suture. No drain is required in the majority of cases.

Postoperative Care and Complications

Postoperatively, patients are positioned in a low Fowler position, with the head and shoulders elevated at least 10 to 20 degrees in order to maintain low venous pressure in the neck. Diet is advanced quickly as the patient emerges from the effects of anesthesia. For patients who have undergone total thyroidectomy, serum calcium levels may be tracked periodically during the hospital stay. Prophylactic oral calcium supplementation can be administered, and additional supplementation may be given for symptomatic hypocalcemia. Prophylactic calcitriol also may be started preoperatively in patients at higher risk of postoperative hypocalcemia, such as those with Graves disease. Some surgeons measure preclosure intraoperative PTH or postoperative intact PTH levels within a few hours of the operation to help guide the dosing of calcium/calcitriol supplementation. There are several variations of these strategies with evidence-based literature, and any one of them would be helpful in the prevention and treatment of postoperative hypocalcemia. Patients who had undergone first-time unilateral lobectomy do not require any biochemical evaluation or calcium supplementation.

The vast majority of patients are discharged within 2 to 24 hours after surgery, with most procedures being performed in the outpatient setting. Patients having undergone total thyroidectomy are prescribed thyroid hormone replacement at a weight-based dose. Some surgeons prescribe a time-limited course of prophylactic calcium supplementation. Opioid analgesics are virtually never needed upon discharge. Most patients can return to work or full activity within 1 week and are typically seen for a postoperative check and pathology review within 2 weeks.

The length of hospital stay after thyroidectomy has evolved. Historically, patients undergoing thyroidectomy have been

observed overnight so that complications, particularly neck hematoma (see later), could be identified and managed expeditiously. Over the past decade, however, outpatient thyroidectomy has become a safe alternative for many selected patients undergoing routine thyroidectomy because the rate and sequelae of neck hematoma have been shown to be acceptable and, like those undergoing thyroidectomy, with at least one overnight stay in the hospital. We would suggest that outpatient thyroidectomy is appropriate for patients who (1) live within driving distance to the hospital, (2) have reliable transportation and adult support at home for at least 24 hours, and (3) do not have significant perioperative comorbidities or take anticoagulants. Patients with Graves disease were previously recommended for overnight observation, but recent studies have demonstrated outpatient thyroidectomy to be a safe practice in this population as well.[70]

Complications

Thyroidectomy is associated with three major complications: vocal cord paralysis from RLN injury, hypoparathyroidism, and postoperative neck hematoma.

Vocal cord paralysis. Rates of temporary and permanent RLN injury during thyroidectomy are in the 4% to 10% and 0.5% to 2% ranges, respectively[71]; rates in the pediatric population are estimated to be up to fourfold higher.[58] Unilateral injury to the RLN and resultant vocal cord paralysis can cause a spectrum of problems with the voice or swallowing because of the mixed motor and sensory fibers within the nerve. Symptoms can include hoarse and breathy voice, vocal fatigue, dysphagia, and aspiration. Rarely, bilateral RLN injury with resultant resting vocal cord position in the midline can lead to airway compromise and can potentially require temporary or permanent tracheostomy. Risk factors for RLN injury include low surgeon volume, reoperative thyroid surgery, more extensive surgery for malignancy, Graves disease, and large substernal goiter.

Injury to the EBSLN also can lead to postoperative voice abnormalities because of its innervation of the cricothyroid muscle and contribution to vocal cord muscle tone. Symptoms of EBSLN injury include vocal fatigue, decreased ability to reach higher pitch, and decreased ability to project the voice. Definitive diagnosis of EBSLN injury is challenging because laryngoscopy is often normal and may require electromyographic studies; as such, estimates of the rate of injury are imperfect and range from 2.5% to 28%.[71]

Hypoparathyroidism. Hypoparathyroidism is the most common complication of thyroid surgery. The rate of temporary hypoparathyroidism is estimated to be as high as 5% to 15%, but the vast majority of these cases resolve within 6 months, leading to a rate of permanent hypoparathyroidism of 1% to 3%.[72] The wide variation in rates is in part because of differences in the definition of hypoparathyroidism in the published literature, which can be based on biochemical evidence of decreased serum calcium and/or PTH levels or symptomatic hypocalcemia requiring calcium or vitamin D supplementation. Risk factors for hypoparathyroidism include bilateral neck exploration, extensive central neck dissection, reoperative surgery, thyroidectomy for Graves disease, and pediatric patients.

The blood supply to the parathyroid glands is extremely delicate and easily injured, so meticulous dissection and preservation of the glands is critical. Although use of parathyroid autofluorescence using near-infrared (NIR) spectrum light holds promise for intraoperative identification and preservation of parathyroid glands, data about their use to prevent postoperative hypoparathyroidism have mixed results, showing no or a small difference.[73]

All thyroidectomy specimens should be checked for inadvertently resected parathyroid tissue; if parathyroid tissue is present and confirmed by either frozen section or intraoperative PTH aspiration, then the parathyroid tissue can be preserved on ice, minced, and autotransplanted into the sternocleidomastoid muscle before closure. Some high-volume endocrine surgical units administer prophylactic calcium with or without calcitriol supplementation in patients undergoing total thyroidectomy, with higher-risk populations (e.g., patients with Graves disease, pediatric patients) receiving preoperative administration as well.[72]

Postoperative neck hematoma. Postoperative neck hematoma occurs in 0.1% to 1.1% of patients undergoing thyroidectomy. Various studies have identified a number of different risk factors for hematoma, particularly male sex, advanced age, bilateral operation, Graves disease, and use of anticoagulants.[74] The danger lies not in the effect of blood loss on circulating blood volume, but rather on the local compressive effect on the trachea leading to rapid airway compromise. Neck hematoma typically presents with pain, oozing from the incision, ecchymosis, and firm swelling overlying the resection bed and incision. Patients can develop stridor with rapid airway collapse.

The vast majority of hematomas occur within the first 6 hours after the operation, 20% of cases occur between 6 and 24 hours, and very few cases occur afterward.[75] The key to management is early recognition and management. Depending on clinical status, the patient can be transported immediately back to the operating room for opening of the incision under a controlled setting with anesthesia availability; however, if the patient exhibits signs of impending airway collapse, the incision should be opened immediately wherever the patient may be. Because of this possibility, instruments for emergent opening of the incision should be present at the bedside at all times. When opening the incision, all three layers to the thyroidectomy bed—the skin, platysma, and strap muscles—must be opened to allow for maximal decompression.

Adjunctive Technologies During Thyroidectomy

Energy Sealing Devices and Hemostatic Agents

Technologies for minimizing the risk of bleeding after thyroidectomy generally fall under two categories: energy sealing devices, which are used as adjuncts or replacements for traditional clamp/tie or clipping methods for ligation of bleeding vessels, and hemostatic agents, which are typically placed on the thyroid resection bed as adjuvant methods mainly for controlling oozing-type bleeding. Energy sealing devices clamp down with force on blood vessels and apply one of two different types of energy—bipolar radiofrequency or ultrasonic vibration—to fuse the clamped tissues together. These devices are used for ligation of major structures such as the superior pole vessels, and some surgeons use them also for dissection of finer vessels around the RLN and the parathyroid glands; however, because their primary limitation is the radial spread of thermal energy and potential for damage to neighboring structures, care must be taken when using them around these critical structures. Multiple meta-analyses have demonstrated that energy sealing devices are associated with equivalent outcomes compared with traditional clamp-tie methods with respect to operative blood loss and rate of postoperative neck hematoma, along with improved operative times.[75]

Hemostatic agents also fall under multiple mechanistic groups: topical hemostats, which facilitate clotting at a bleeding surface; sealants, which prevent leakage from vessels; and adhesives, which bond tissues together. Different products can have overlapping mechanisms. A recent meta-analysis grouping studies of all hemostatic agents together showed improvements compared with conventional hemostatic methods in terms of drain output and length of postoperative hospital stay, but no significant differences were observed in the risk of hematoma formation.[76]

Intraoperative Neuromonitoring

IONM systems for the RLN involve the use of electrical stimulator probes to deliver electrical current to the vagus nerve or RLN, which leads to an electromyographic signal at the vocal cord detected by contact electrodes embedded on the surface of the endotracheal tube. All IONM systems use intermittent direct stimulation of the vagus and RLN with electrical current delivered via contact probe before, during, and after thyroid resection; some surgeons also add continuous stimulation of the vagus nerve via a flexible cuff electrode to monitor for fluctuations in the quality and integrity of the nerve signal in real time during the dissection. The IONM systems also can be used to stimulate and test integrity of the EBSLN.

The adoption of IONM has increased over the past 15 years, and in some countries, the routine use of IONM is mandatory. Despite the widespread adoption, the added benefit of IONM for reducing the risk of RLN injury remains controversial. Although multiple systematic reviews and meta-analyses have historically failed to demonstrate a significant benefit of routine IONM in reducing RLN injury rates during thyroidectomy, more recent data from multiple studies suggest that IONM was independently associated with reduced risk for short- and long-term vocal cord dysfunction.[77] Proponents of IONM cite its benefit in higher-risk operative scenarios, such as reoperative surgery, surgery for malignancy, thyrotoxicosis, or substernal goiter,[78] and the reduction in the risk of bilateral RLN injury.

The 2018 guidelines from the International Neural Monitoring Study Group recommend standardized IONM practices during thyroidectomy, which include the following steps:

1. Initial vagal nerve stimulation to confirm intact RLN function and electrode position
2. Visual identification and direct stimulation of the RLN during the course of thyroid lobectomy
3. Final reconfirmation of intact RLN function with vagal nerve stimulation after completion of thyroid lobectomy

In addition, the International Neural Monitoring Study Group guidelines highlight the importance of surgeons' practicing and familiarizing themselves with IONM to be able to comprehensively troubleshoot equipment issues from true loss of RLN-signaling events.[79]

Fluorescent Imaging Aids for Parathyroid Identification

Because parathyroid identification during thyroidectomy is critical for the prevention of hypoparathyroidism, there has been renewed interest in newer technologies for intraoperative parathyroid imaging. The most prominent technologies under investigation currently are those that detect fluorescence from the parathyroid.

Parathyroid tissue autofluoresces in the NIR spectrum when exposed to a laser at a wavelength of 285 nm. Since this discovery in 2011, subsequent studies have demonstrated that parathyroid autofluorescence can be reliably detected both ex vivo and in vivo. Detection can either be done by spectroscopy using a contact probe or specialized NIR spectrum cameras, with parathyroid glands that can be located in 76% to 100% of cases.[80] The potential advantages of this technology are its noninvasiveness and avoidance of an exogenously administered fluorophore. Current disadvantages include its limited penetration to up to only a few millimeters' depth; subtle and subjective fluorescence images with current-generation cameras and image processing software, including false positives from brown fat and metastatic lymph nodes; and requirement for white (visible-spectrum) light to be turned off or minimized for the signal to be detected.

Exogenously administered fluorophores can aid in identification by more dramatically fluorescing the parathyroid glands. The fluorophore of greatest interest currently is indocyanine green, a water-soluble tricarbocyanine dye that rapidly binds to proteins in plasma after IV injection. Indocyanine green is a commonly used dye with low toxicity and a variety of clinical uses in other surgical procedures, and its use has been studied in both thyroidectomy and parathyroidectomy.

Alternative Approaches to Thyroidectomy

The techniques detailed earlier describe conventional thyroidectomy via an open, anterior cervicotomy approach that has become the standard of care worldwide. As techniques have been refined and technologies have improved, various efforts to minimize the cosmetic effect of a visible neck incision have been investigated. From a historical perspective, the most direct and straightforward means to this end was to decrease the length of the standard cervicotomy incision from 6 to 8 cm down to 3 to 4 cm using traditional instruments and 1.5 to 2.5 cm with the aid of endoscopic instruments. A number of variations have been described with differing terminology, including *minimally invasive, video-assisted, videoscopic/endoscopic,* and *mini-open,* all of which have demonstrated reasonable feasibility and safety in carefully selected patients.

In addition, various investigators have described nontraditional techniques that place incisions in hidden places away from the visible part of the neck, with subcutaneous and/or subplatysmal dissection using minimally invasive surgical instruments to the thyroidectomy area of interest. These so-called “remote access” approaches have largely been developed and widely adopted in Asia and have subsequently established a small but growing niche in the United States and Europe. All require the use of either laparoscopic or robotic instruments, and virtually all can be performed using insufflation of a closed space with CO_2 gas or with a gasless technique using custom long-tunneled retractors.

There are several different remote access approaches described in the literature differentiated by where the “hidden” incision is placed; the most common sites are the axilla, nipple-areolar complex or chest, retroauricular area at the hairline (the so-called “facelift” approach), and oral cavity. The most common approaches in the United States are the axillary and transoral approaches.

Transaxillary thyroidectomy using laparoscopic instruments via three small port incisions was first described in Japan in 2000 but first gained traction in the United States in 2007 based on excellent results from South Korea using a robotic, gasless technique with a single incision in the axilla. The initial American experience was marked by an upsurge of complications, including brachial plexus injury, tracheoesophageal injury, lymph leak, and hematoma, which was exacerbated by a combination of inadequate surgeon training and aggressive marketing by the medical device industry. After issuance of warnings by the US FDA in 2013, the manufacturers of the da Vinci surgical robotic system (Intuitive Surgical, Sunnyvale, CA) withdrew active support for robotic thyroidectomy, which led to an abrupt plateau in the adoption of robotic thyroidectomy cases. Since this initial turbulent experience, robotic transaxillary thyroidectomy has benefited from systematic study and steadier reintroduction in only a handful of more experienced centers. A recent experience of 301 cases in the United States revealed excellent technical feasibility (one conversion to open thyroidectomy) and safety (1.3% permanent RLN injury, 1.1% permanent hypoparathyroidism, 0.3% neck hematoma), with only one patient suffering from an approach-specific complication (arm lymphedema, which resolved with conservative management) and no recurrences among the 133 patients who had cancer identified histologically.[81]

Among all of the remote access approaches, only the transoral route offers the potential of avoiding an incision at the skin altogether. However, there were many theoretical concerns around removing the thyroid through the mouth, not least of which was introducing a new risk of infection from oral flora and injury to other structures in the oral cavity as well as at the chin. The most adopted technique was popularized in Thailand and uses laparoscopic instruments and gas insufflation via three small port incisions in the oral vestibule (Fig. 73.36). The largest published experience is a 425-patient case series from Thailand revealing zero cases of permanent RLN injury or permanent hypoparathyroidism, one case of neck hematoma requiring open thyroidectomy, and three intraoperative conversions to open thyroidectomy. With respect to approach-specific complications, three patients (0.7%) had transient mental nerve palsy, and no patients experienced a postoperative infection.[82] Other groups have replicated these results.

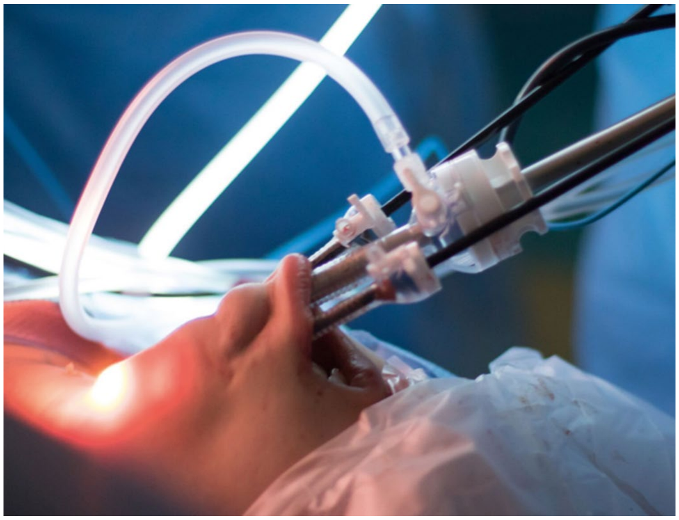

FIGURE 73.36 Transoral endoscopic thyroidectomy vestibular approach. Three laparoscopic ports are placed in the oral vestibule, and dissection is carried out down to the subplatysmal plane in the neck.

These excellent results have led to early adoption of the technique in the United States. However, with lessons learned from prior experiences around the rollout of transaxillary thyroidectomy, greater efforts are in place to introduce this technique in a more organized and responsible manner. Greater emphasis now exists on ensuring proper training, credentialing, and outcomes-tracking procedures for surgeons, and adoption is mainly occurring in larger, high-volume institutions at this time. Based on broad consensus, the selection criteria for transoral thyroidectomy have remained relatively constrained in the early phase of its adoption. It is with these quality control efforts that transoral thyroidectomy—and other future innovations—will be introduced in a manner that both fosters innovation and protects patient safety.

Thyroid Ablation Techniques

Ablation techniques have been recognized as an effective method for reducing thyroid nodule volume while preserving thyroid function, predominantly in benign disease states. Ablation techniques employ either chemical ablation or thermal ablation to achieve thyroid nodule volume reduction.

Chemical ablation is typically performed by injecting 95% to 99% dehydrated alcohol into a thyroid nodule under ultrasound guidance. Ethanol is left in situ or aspirated out after a period of time. Ethanol causes coagulative necrosis via cellular dehydration and ischemic necrosis via small vessel thrombosis, which in turn causes nodule volume reduction. Ethanol ablation is an effective technique for predominantly cystic nodules, which can recur if simply aspirated.

Thermal ablation uses different energy mechanisms to heat tissue and cause coagulative necrosis. It is best suited for patients with compressive symptoms or cosmetic complaints that can be attributed to a single or dominant thyroid nodule. Thermal ablation techniques include radiofrequency ablation, laser ablation, microwave ablation, and high-intensity focused ultrasound.

- Radiofrequency ablation uses a high-frequency alternating current (200–1200 kHz) to agitate tissue ions and cause heat production.

- Laser ablation uses single or multiple optical fibers to create a focused beam of light energy onto tissue, which causes heat.
- Microwave ablation generates an electromagnetic field (900–2500 MHz) to oscillate polar water molecules and generate heat.
- High-intensity focused ultrasound delivers ultrasound waves to generate heat at a target location, which then causes formation of microbubbles. Expansion and collapse of microbubbles induce hemorrhage through cavitation.

Radiofrequency Ablation

Symptomatic, nonfunctional, benign thyroid nodules are the most widely accepted indication for radiofrequency ablation. Thyroid nodules should appear with a very low to low suspicion for malignancy by the ATA classification for thyroid nodules (ACR TI-RADS 1, 2, or 3) or intermediate suspicion (ACR TI-RADS 4) with benign cytology. Two benign biopsies of the thyroid nodule are recommended before ablation. Functional nodules may be ablated, but resolution of hyperthyroidism is less predictable than after RAI or surgery. Therefore, RFA is considered best for patients with small toxic adenomas and contraindications to RAI or surgery.

RFA has been explored for treating indeterminate nodules and primary thyroid cancer, but it is not considered a first-line treatment currently for these indications. Because RFA does not allow for histologic analysis, nor does it prevent metastasis, it is not recommended for indeterminate nodules. Incomplete RFA treatment in other tumor types has led to tumor progression. Although RFA has been used to treat recurrent PTC and PTmC, further investigation is needed before considering RFA as a first-line treatment in malignant thyroid disease.

For benign thyroid nodules, RFA can effectively reduce nodule volume by 65% at 6 months and 77% at 12 months. Nodule volume reduction is also accompanied by improvement in local compressive symptoms and cosmesis. Compared with surgery, RFA is associated with improved preservation of thyroid function and better health-related quality of life.

Like any other procedure, RFA also introduces potential complications. There is risk of RLN injury, as in surgery, because of proximity of the RLN to the thyroid. Accurate RLN injury rates are currently lacking; one systematic review and meta-analysis identified a 1.4% rate of subjective voice change (temporary or permanent) after RFA.[83] Thyroid nodule rupture, thought to be caused by delayed bleeding resulting in thyroid capsule disruption, is the second most common complication after voice change. Hematoma can occur if an anterior jugular vein or a significant perithyroidal vein is crossed with the probe. Tracheal necrosis or airway compromise can occur from penetration or ablation near the trachea.

As thermal ablation techniques such as RFA have been introduced in North America, the ATA and international thyroid societies have recently released guidelines for safe adoption.[84] Clinicians interested in incorporating thermal ablation techniques into their practice are recommended to have comprehensive knowledge and experience in the management of thyroid nodules, neck anatomy, ultrasound imaging and FNA of the thyroid, and ultrasound risk stratification of thyroid nodules. Training should include extensive practice on phantom models, and initial thyroid nodule ablation should be performed with a proctor.

Health Equity in Thyroid Disease

The presence of disparities in care related to thyroid cancer has recently come to light. Given the indolent nature and favorable prognosis of most DTC, this disease process is somewhat unique, in that disparities in access to care may result in overdiagnosis and overtreatment of advantaged groups while simultaneously leading to underdiagnosis and undertreatment of disadvantaged groups.[85] Indeed, health insurance coverage has been shown to have a direct correlation with thyroid cancer incidence[86]; uninsured or otherwise socioeconomically disadvantaged patients have higher rates of negative prognostic indicators such as lymphovascular invasion, extrathyroidal extension, positive margins, and distant disease.[87] Socioeconomic status (SES), race, and ethnicity predict access to care and advanced presentation. Patients who are uninsured or underinsured are less likely to undergo total thyroidectomy, have formal lymphadenectomy, and adjuvant RAI than patients with private insurance, whereas Black patients, those >65 years of age, and with lower SES are less likely to be treated in accordance with ATA guidelines.[88] Sadly, this also translates into patient outcomes, with Black patients suffering higher 5-year mortality from DTC than White patients, even after adjustment for SES plus tumor- and treatment-related variables.[89] Davis and colleagues proposed strategies that can be used to combat health disparities in thyroid cancer diagnosis and treatment, including expanding Medicaid, providing insurance reimbursement for travel and other ancillary expenses, avoiding unnecessary in-person visits, and expansion of access to high-volume experts, including across states.[85]

HISTORY OF PARATHYROID SURGERY

In 1850, Sir Richard Owen, professor of the Royal College of Surgeons of England, presented the first record of what is now accepted as a parathyroid gland. He described, within an Indian rhinoceros, the dissection of a “small, compact yellow glandular body attached to the thyroid at the point where the vein emerged.” Although others later described similar structures in other animals, it was ultimately Swedish medical student Ivar Victor Sandstrom who first described “glandulae parathyroideae” in a series of 50 human cadavers in 1880.

In 1879, Theodore Billroth performed a total thyroidectomy that was complicated by tetany. Anton Wolfer recognized the condition as the result of surgery but did not directly implicate the parathyroid. Eugene Gley, a physiologist at the College de France in Paris, reported fatal tetany after parathyroidectomy and thyroidectomy in animal models in 1891. Frederick von Recklinghausen first described osteitis fibrosa cystica that same year. The first decade of the 20th century saw a bevy of advancements in parathyroid physiology. Max Askanazy linked osteitis fibrosa cystica to parathyroid hormone (PTH), and Jacob Erdheim provided one of the earliest descriptions of parathyroid enlargement with a series of six autopsies of persons afflicted with osteomalacia. In 1909, Berkeley and Beebe used bovine parathyroid extract to alleviate parathyroidectomy-induced tetany.[1] In this era, a common hypothesis was that parathyroid hyperplasia was compensatory to bone disease and that parathyroid glands detoxified plasma of excess calcium. Indeed, biochemist James Collip first patented parathyroid extract in 1925 as a treatment for osteitis fibrosa cystica. Contesting this theory was Viennese pathologist Friedrich Schlagenhaufer, who suggested in 1915 that parathyroid hyperplasia was not a sequela of bone disease but rather its instigator. Hyperparathyroidism became more readily diagnosed after the invention of the autoanalyzer by Leonard Skeggs in 1951.[2] Increased awareness of hypercalcemia led to recognition of parathyroid hyperactivity as its most common cause.

The history of parathyroidectomy is almost as long as that of PTH itself. William Halsted described autotransplantation of parathyroid tissue in a dog model in 1907, a practice that remains relevant today. Although incidental parathyroidectomy during thyroidectomy has been described since the late 1800s, the origin of *intentional* parathyroidectomy remains contested. Bland Sutton in London described resection of an infero-thyroidal mass causing airway obstruction sometime before 1918. This was reported to have been a parathyroid post hoc. However, the first parathyroidectomy performed for hypercalcemia is typically attributed to Viennese surgeon Felix Mandl. The patient, Albert Gahne, presented with osteitis fibrosa cystica in 1925. Mandl first acted on Collip’s theory of detoxification and transplanted four cadaveric parathyroids into Gahne’s rectus, to no avail. He then tested Schlagenhaufer’s theory by performing a cervical exploration. This resulted in resection of a 2.5-cm mass caudal to the thyroid. Gahne improved dramatically but recurred 6 years later and died after a futile reexploration. Early surgical philosophy for the treatment of hyperparathyroidism strongly favored subtotal parathyroidectomy (SPTX) to minimize delayed recurrence despite a 10% rate of postoperative tetany.[2] This dogma was challenged by Oliver Cope, who in 1958 reported that nearly 80% of cases were due to single-gland hyperplasia. In subsequent years, SPTX became recategorized as the preferred treatment for secondary hyperparathyroidism (SHPT) due to vitamin D deficiency or renal insufficiency.

Parathyroid localization has been a unique surgical challenge for nearly a century. US merchant marine captain Charles Martell famously presented to Massachusetts General Hospital in 1926 as the first American patient diagnosed with hyperparathyroidism. He reportedly underwent five futile explorations before a 3-cm parathyroid adenoma (PA) was removed from his mediastinum.[3] The first successful parathyroidectomy for hyperparathyroidism in the United States is credited to Isaac Olch, who removed a 3-cm parathyroid tumor from an Illinois farmer, Elva Dawkins, at Barnes Hospital in St. Louis in 1926. As selective parathyroidectomy slowly became the preferred treatment for primary hyperparathyroidism (PHPT) in the 1950s, preoperative parathyroid localization gained subsequent appeal. Parathyroid localization in its modern form evolved from parathyroid ultrasonography in the 1960s to include molecular imaging in the 1970s and, ultimately, four-dimensional computed tomography (4D CT) in 2006. Complementing these technologies was the advent of intraoperative PTH measurement as a surgical adjunct in 1988—the final piece to shape today's widespread practice of targeted parathyroidectomy.

EMBRYOLOGY

Understanding parathyroid embryology provides insight into the parathyroid's surgical anatomy and its operative approach. Pharyngeal pouches are bilateral endodermal protrusions lateral to the pharynx derived from epithelium surrounded by neural crest–type mesenchymal cells. Human parathyroids develop from the third and fourth pharyngeal pouches, with differentiation driven by drosophila glial cell missing gene *(GCM2),* which is also a requisite for PTH production (Fig. 74.1). Mutations in *GCM2* in humans can result in hypo- or hyperparathyroidism and are one genetic contributor to familial isolated hyperparathyroidism.

The third pharyngeal pouch gives rise to the thymus and inferior parathyroids, whereas the superior parathyroids and lateral thyroid originate from the fourth pharyngeal pouch. Separation and caudal migration of the thymic-parathyroid primordium away from the pharynx occurs in the fifth and sixth weeks of gestation.[4] Once parathyroid and thymus separate, the thymic lobes continue their migration into the mediastinum, leaving the inferior parathyroids behind in the lower neck. The variable timing of this separation is believed to contribute to the well-reported anatomic distribution of ectopic inferior parathyroids, the most common location of which is intrathymic. The migration may also leave a "trail" of *GCM2*-positive cell clusters along the path of descent, providing one theoretical explanation for cases of supernumerary parathyroids. In a similar pattern, the paired superior parathyroids separate from the fourth pharyngeal pouch in conjunction with the lateral thyroid and travel caudally in unison. Because of the shorter distance of travel and less variable timing of separation, the superior parathyroids are less frequently ectopic and more likely to be found within the capsule of the upper poles of the thyroid.

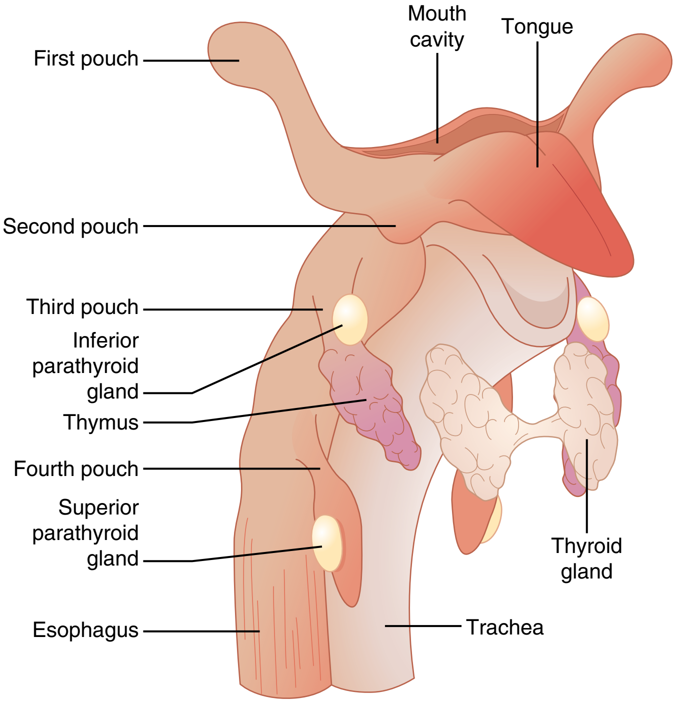

FIGURE 74.1 The pharynx and adjacent structures are depicted between the sixth and seventh weeks of embryologic development. The thyroid gland has descended to its normal location in the neck. The inferior parathyroid glands and thymus are seen arising from the third pharyngeal pouches. The superior parathyroid glands are seen arising from the fourth pharyngeal pouches.

HISTOPATHOLOGY

Grossly, normal parathyroids are typically smooth, soft, ovoid or lenticular structures measuring roughly 5 × 3 × 2 mm in dimension with a yellow-tan appearance (Fig. 74.2). Fat content increases with age; thus, older patients tend to have glands with a paler-yellow appearance compared with younger counterparts, in whom the glands are typically reddish brown. Typical weight is 30 to 40 mg but highly variable. Frozen section is occasionally used intraoperatively to differentiate parathyroid from a thyroid rest, lymph node, or perithyroidal fat. In this context, parathyroid typically lacks the calcium oxalate crystals detectable with polarized light microscopy in thyroid tissue and has more structure and cellular clustering than the scattered lymphocytes and histocytes found in lymph nodes.

On microscopy, the parathyroid is encapsulated, with septa that divide the parenchyma into ill-defined lobules. The dominant cell types are chief cells and oxyphil cells. Chief cells are round with centrally located nuclei and small nucleoli. Cytoplasm is typically clear or faintly eosinophilic and often contains lipids that give it a slightly vacuolated appearance. They are the primary functional cell type in the gland and are responsible for PTH synthesis and secretion. Oxyphils are larger than chief cells and are arranged in clusters or sheets. As their name indicates, these cells contain a granular eosinophilic cytoplasm with abundant mitochondria.

In contrast to normal parathyroids, PAs typically weigh 200 mg to several grams and vary greatly in dimension. Grossly, PAs are well circumscribed, smooth, and may contain hemorrhagic or cystic components. Stromal fat content is lower than normal

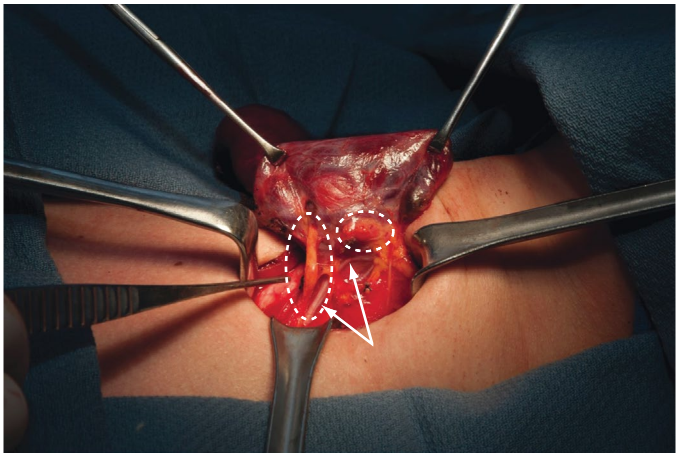

FIGURE 74.2 Intraoperative photograph demonstrating normal left superior and inferior parathyroid glands surrounded by adipose tissue and their relationship to the thyroid and the recurrent laryngeal nerve (*right side* of image is rostral, and *left side* is caudal; *dashed lines* encircle the parathyroid glands, and the *arrows* point to the left recurrent laryngeal nerve).

glands, lending the PA its red-brown coloration even in older patients. A rim of normal parathyroid tissue is often noted on pathology reports. Cellular atypia—usually indicated by enlarged, irregular, or multiple nuclei—does not imply a malignant or premalignant lesion. However, PA cells usually show low mitotic activity (<1 per 10 hpf), and findings of increased mitotic activity or necrosis should raise suspicion of carcinoma or atypical tumor.[5]

Parathyroid hyperplasia is a diffuse increase in parenchymal cell content, which can include proliferation of chief cells, oxyphils, or both in several or all parathyroid glands. When hyperplasia is unequal across all four glands, gross differentiation from adenoma can be challenging. This is particularly true if a clear secondary etiology for hyperplasia is unable to be established. Although the prevailing view is that most PAs are monoclonal cellular proliferations, recent data suggest that a substantial number of parathyroid tumors are polyclonal and that polyclonal tumor status is associated with multiple-gland disease.[6]

Parathyroid carcinoma (PCA) is among the rarest malignancies in humans and accounts for less than 1% of cases of PHPT. Grossly, PCA is characterized by obliteration of capsule and tissue planes and infiltration into surrounding structures such as the thyroid, fat, trachea, recurrent laryngeal nerve, or esophagus. According to the World Health Organization (WHO), histology diagnosis of PCA requires at least one of the following conditions: (1) angioinvasion, (2) lymphatic invasion, (3) perineural invasion, (4) invasion into adjacent structures, or (5) metastatic disease. In intermediate cases of clear cellular atypia in the absence of one of the aforementioned criteria—that is, increased mitotic activity (>5 per 10 hpf) and/or Ki67 index (>5%)—the WHO applies the term *atypical parathyroid tumor*.[7] Additional features include sheetlike growth pattern, consistent nuclear atypia, and the presence of intratumoral fibrous bands. The change from the prior nomenclature of *atypical parathyroid adenoma* to *atypical parathyroid tumor* reflects the recognition that the boundary between these diagnoses is most likely a continuum, and metastatic recurrence in atypical adenoma has been reported. In recent years, advanced immunohistochemical markers have further assisted in differentiating between benign and malignant cases. Adenomas typically retain expression of parafibromin, retinoblastoma protein (RB), and adenomatous polyposis coli protein (APC). Loss of expression of these markers, overexpression of p53, and Ki-67 index >5% combine to favor a diagnosis of atypical parathyroid tumor or PCA.

PHYSIOLOGY

Within parathyroid chief cells, PTH is created through cleavage from pre-pro-PTH and stored in its biologically active form, intact PTH. This ready supply facilitates secretion within seconds and, together with the hormone's rapid extracellular degradation, allows for exquisite regulation of serum calcium. Renal and hepatic metabolism cleaves intact PTH into carboxyl- and amino-terminal fragments. Intact PTH has a plasma half-life of 3 to 4 minutes, a feature that greatly facilitates intraoperative decision-making through venous sampling of PTH level.

PTH is regulated predominantly by serum calcium via the calcium-sensing receptor (CaSR), which is a dimerized G protein–coupled receptor that acts on downstream kinases, including protein kinase C, $ERK_{1/2}$, p38, and JNK.[8] The net result is inhibition of both PTH synthesis and secretion and activation of intraglandular PTH degradation. The relationship between serum calcium and PTH levels is often described as an inverse sigmoidal curve (Fig. 74.3). The steep midportion of the curve alludes to a physiologic calcium set point around which the PTH response to calcium concentration is greatly magnified. In normal conditions, calcium fluctuation by 0.1 mg/dL can induce a noticeable change in PTH concentration within minutes. For example, when serum calcium is below the physiologic set point, CaSR-mediated responses include increased intact PTH secretion from parathyroid chief cells, inhibition of PTH cleavage into inert carboxy-terminal fragments, stabilization of PTH mRNA, and chief cell proliferation.[9]

Additional PTH regulators include phosphate and calcitriol. Phosphate stimulates PTH secretion and chief cell proliferation both directly and indirectly through induction of hypocalcemia. The mechanism of direct stimulation is thought to be due to noncompetitive inhibition of CaSR.[10] This phenomenon is important because persistent hyperphosphatemia is thought to be

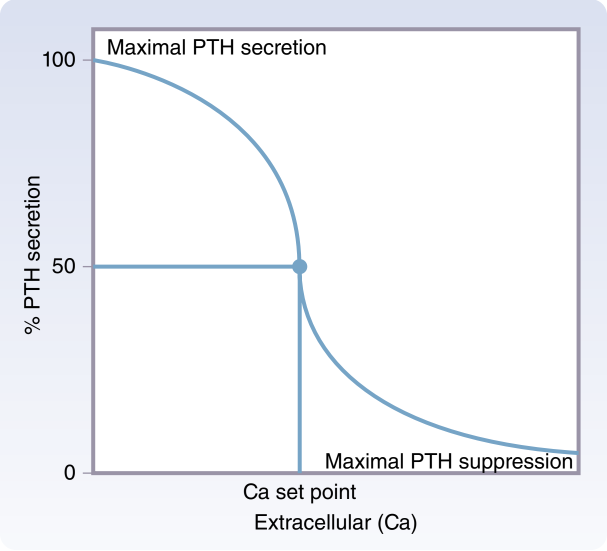

FIGURE 74.3 Inverse sigmoidal relationship of parathyroid hormone *(PTH)* to changes in extracellular calcium concentration and the calcium set point. *Ca*, Calcium.

one of the principal drivers of SHPT in the setting of chronic kidney disease (CKD). Calcitriol (1,25(OH)2D3) reduces PTH production and secretion by binding vitamin D receptors on chief cells to suppress PTH gene expression and by upregulating expression of CaSR. In the setting of CKD, there is a reduction in both renal conversion of 25(OH)D3 into calcitriol and chief cell vitamin D receptor expression, considerably stunting calcitriol's inhibitory effect.[11] Finally, fibroblast growth factor-23 (FGF23) promotes renal phosphate wasting, which results in decreased PTH secretion. Although parathyroid does express the FGF23 receptor αKlotho, whether FGF23 has a direct inhibitory effect on parathyroid secretion remains unclear.

PTH-mediated calcium regulation is enacted primarily through activation of receptor PTH1R, which binds both PTH and PTH-related protein (PTHrP). PTH1R binds to the amino-terminal section of PTH, which is structurally similar in PTHrP. Although the carboxy-terminus of PTH is classically thought of as inactive, there is mounting evidence that this fragment antagonizes PTH-mediated effects and induces hypocalcemia by inhibiting bone resorption.

In skeletal bone, stimulation of PTH1R results in maturation of osteocytes into mature osteoblasts that function to increase bone formation. However, PTH also indirectly mediates bone resorption through osteoclast-activating regulators produced by osteoblasts and progenitors. These include receptor activator of nuclear factor-kappa B (RANK), its corresponding ligand RANKL, and osteoprotegerin. The anabolic effect dominates in the setting of transient or intermittent PTH elevation, justifying the use of recombinant PTH in treatment of osteoporotic postmenopausal females. Conversely, the catabolic effect dominates when PTH is chronically elevated, as is the case in osteoporosis as a result of PHPT or SHPT.

In the nephron, most filtered ionized calcium is reabsorbed by the proximal tubule via sodium-dependent passive transport. Although PTH does not directly modulate calcium transport in this segment, there is clear evidence that it inhibits sodium reabsorption. This may indirectly lead to reduced calcium reabsorption; however, in vivo studies have yielded variable results to date.[12] Phosphate is also predominantly reabsorbed in the proximal tubule, and there is strong evidence that PTH inhibits this process and induces phosphate wasting. This occurs through a reduction in apical membrane expression of sodium phosphate cotransporters NaPi-2a, NaPi-2c, and PiT2. Lastly, the proximal tubule is the principal site of conversion of inactive 25(OH)D3 into active calcitriol via 1-α hydroxylase. PTH stimulates synthesis of 1-α hydroxylase and inhibits the activity of 24-hydroxylase, the cumulative effect of which is an increase in serum concentration of biologically active calcitriol (Fig. 74.4).

The distal convoluted tubule is responsible for reabsorbing roughly 5% of filtered calcium via active transport. The primary apical channel that drives calcium uptake from the lumen is transient receptor potential vanilloid 5 (TRPV5). Once intracellular, calcium is shuttled to the basolateral membrane and secreted via a sodium-calcium exchanger (NCX1) and calcium-ATPases (PMCA4). Within the distal convoluted tubule, PTH binding to PTH1R enhances TRPV5 expression and regulates TRPV5

function through hormone-dependent phosphorylation via protein kinase A. Finally, PTH stimulates conversion of 25(OH)D3 into calcitriol, which itself also amplifies TRPV5 expression. The net effect is dramatically increased apical membrane uptake and transcellular shuttling of calcium from the lumen to the basolateral membrane.[12]

PRIMARY HYPERPARATHYROIDISM

Epidemiology

Before the introduction of the chemistry autoanalyzer in 1974, PHPT typically presented with symptomatic hypercalcemia. After this breakthrough, and with increasing attention to osteoporosis screening in recent decades, detection of PHPT gradually rose. Recent estimates among the US population indicate a prevalence of 233 per 100,000 in females and 85 per 100,000 in males. Overall incidence is roughly 50 cases per 100,000 person-years. Incidence increases with age across both sexes and is highest among African American females.[13] Childhood exposure to ionizing radiation increases the risk of PHPT in later years. Lithium decreases CaSR sensitivity to calcium, thereby dampening negative feedback and promoting PHPT. Familial syndromes that involve PHPT with variable penetrance include multiple endocrine neoplasia (MEN) type 1, hyperparathyroidism–jaw tumor syndrome (HPT-JT), MEN2A, MEN4, and familial isolated primary hyperparathyroidism (FIHP). Corresponding germline mutations are *MEN1* (MEN1), *RET* (MEN2A), *CDKN1B* (MEN4), *CDC73* (hyperparathyroidism–jaw tumor), and *GCM2* or *CASR* (FIHP).

Pathophysiology

At its core, PHPT entails a disconnect in the physiologic feedback relationship between calcium and PTH secretion, resulting in an increase in the concentration of calcium necessary to suppress PTH. This may be due to chief cell proliferation or a decrease in the concentration of CaSR within the parathyroid, ultimately resulting in one of three biochemical patterns. In most cases, PHPT manifests with hypercalcemia and elevated PTH. However, PTH may be inappropriately normal (>20 pg/mL) in a patient with hypercalcemia (normohormonal PHPT) or inappropriately elevated in a patient with high-normal calcium (normocalcemic PHPT).

Before the modern era of biochemical screening and testing, PHPT often manifested with recurrent nephrolithiasis or osteitis fibrosa cystica. Additional symptoms include polyuria, polydipsia, constipation, pancreatitis, and renal deficiency. Osteitis fibrosa cystica is characterized by chronic bone pain, pathologic fractures (usually vertebral), bone cysts, and brown tumors. It is now rarely observed in developed nations because most cases of PHPT are diagnosed well before this terminal manifestation. Patients presenting with this symptom profile have usually undergone exhaustive testing for PHPT and should raise suspicion of alternative causes, such as mutations in *FGF23*.

Pathologically elevated PTH chronically activates PTH1R, resulting in bone resorption, increased calcium resorption from the distal convoluted tubule, phosphaturia, and elevated synthesis of 1,25(OH)2D3. There is preferential loss of bone density at cortical sites, most prominently in the distal radius. However, there is evidence that PHPT induces trabecular deterioration in the vertebrae as well, and there is an increased risk of vertebral fracture despite relative preservation in vertebral bone density on dual-energy x-ray absorptiometry (DXA).[14]

About 10% of patients with PHPT present with, or have a history of, nephrolithiasis. Rate of asymptomatic nephrolithiasis is likely significantly higher, and there are proponents of screening renal ultrasound for patients newly diagnosed with PHPT. Of note, nephrolithiasis in the setting of PHPT is not itself associated with reduced estimated glomerular filtration rate (eGFR); however, renal insufficiency is more common among patients with PHPT (15%) than among the general population. Mechanisms for PTH-mediated renal insufficiency are under investigation; current theories include impaired filtration secondary to nephrocalcinosis and hypercalcemia-induced sodium excretion that leads to a reduction in total body water.[14] This effect appears to be quite gradual, and two small, randomized trials comparing surgery versus observation for asymptomatic PHPT failed to show improvement in eGFR after parathyroidectomy at 1- and 2-year follow-up.

Manifestations of PHPT outside of the skeletal and renal systems have been extensively reported but are difficult to prove. These “soft” signs include neuropsychologic findings such as anxiety, cognitive dysfunction, and fatigue thought to be mediated by dysregulation of neurotransmitter synapses because of hypercalcemia. Although observational studies have suggested that these symptoms improve after parathyroidectomy, prospective data have been inconclusive. Similarly, large observational studies have suggested an increased risk of cardiovascular mortality in patients with severe PHPT, possibly mediated by increased vascular stiffness or valve calcification. Whether these risks are meaningful in mild PHPT—which constitutes most modern diagnoses—and whether they are reversible with surgical therapy is unknown. Finally, variable associations have been made between PHPT and gastrointestinal symptoms such as chronic constipation, pancreatitis, and peptic ulcer disease. Ultimately, however, consensus criteria for surgical referral focus on skeletal and renal sequelae (discussed later) because these are supported by more consistent scientific evidence and are more conducive to measurement and follow-up.

Given the unclear cause-and-effect relationship between the biochemical abnormality of PHPT and signs and symptoms of the disease as well as the increased appreciation of multiple-gland disease in series of bilateral exploration compared with unilateral exploration, it is debated whether all cases of apparent PHPT are in fact primary as opposed to polyclonal expansion of chronically stimulated parathyroid glands from a yet-unrecognized metabolic process involving bone and/or kidney.

Diagnosis

Diagnostic and treatment evaluation for PHPT should always incorporate three essential and independent components. The first is to confidently establish a diagnosis of PHPT via a thorough history, physical exam, and biochemical evaluation. Imaging of any form does not contribute to this first step. Upon establishing the diagnosis, the second step is to determine whether a patient possesses a meaningful indication for parathyroidectomy. Only after affirming both the diagnosis and surgical indication does parathyroid localization commence as the third and final step in workup.

Diagnosis of PHPT typically starts with either the recognition of classical PHPT symptoms (osteoporosis, pathologic fractures, recurrent nephrolithiasis, bone pain) or a biochemical profile showing hypercalcemia. Hyperparathyroidism and malignancy are the two most common causes of persistently elevated serum calcium. Other causes, which are readily excluded by a thorough history, include vitamin D intoxication, chronic granulomatous disease, and calcium-boosting medications such as lithium and thiazide diuretics.

A typical initial biochemical panel for evaluation of hypercalcemia includes a comprehensive metabolic panel, total serum calcium, intact PTH, and 25(OH)D3. Non–parathyroid-mediated hypercalcemia is usually associated with suppressed PTH (<20 pg/mL). Elevated PTH or inappropriately normal PTH (>20 pg/mL) in the setting of hypercalcemia is usually indicative of PHPT. Marked PTH elevation (>150 pg/mL) should raise consideration for either PCA or renal insufficiency, although benign PHPT remains the most likely diagnosis. Differential diagnoses also include vitamin D deficiency and familial hypocalciuric hypercalcemia (FHH). Normal or elevated 25(OH)D3 excludes SHPT caused by vitamin D deficiency. If 25(OH)D3 is low, intact PTH should be repeated once vitamin D is repleted. There is little role for ionized calcium in the workup for PHPT; however, one may consider this as an adjunct in the diagnostic evaluation of normocalcemic hyperparathyroidism.

For patients with hypercalcemia and normal or mildly elevated PTH, 24-hour urinary calcium is recommended to rule out FHH. Elevated or normal 24-hour urinary calcium is consistent with PHPT, whereas calcium excretion <100 mg over 24 hours is suggestive of FHH. Calcium-creatinine clearance ratio (CCCR) can further aid in FHH diagnosis and is calculated as CCCR = (24-hour urine Ca × serum Cr) ÷ (serum Ca × 24-hour urine Cr). CCCR <0.01 is the most frequently quoted threshold for diagnosis of FHH; however, there is considerable overlap with PHPT. Vitamin D repletion must be ensured when interpreting CCCR, and confirmatory genetic testing for CaSR mutations is recommended to definitively establish FHH.[15] This workup is ultimately meaningful, however, because FHH is a benign hypercalcemic condition that has no deleterious repercussions and is not improved by parathyroidectomy. Along with serum 25(OH)D3, 24-hour urine calcium can also help differentiate between PHPT and SHPT due to renal insufficiency, particularly for cases of normohormonal hypercalcemia. In the latter condition, both 25(OH)D3 and urinary excretion are typically low.

Surgical Indications

There is general consensus that patently symptomatic PHPT—kidney stones, pathologic fractures—should undergo definitive surgical treatment with parathyroidectomy. However, in the modern era of pervasive biochemical testing, most patients present with asymptomatic PHPT detected via workup for incidentally discovered hypercalcemia. For these patients, both the American Association for Endocrine Surgery (AAES) and the American Society for Bone and Mineral Research (ASBMR) recommend definitive surgical treatment for any patient who satisfies one or more of the following criteria[16]:

1. Serum calcium exceeding upper limit of normal by ≥1.0 mg/dL (0.25 mmol/L)
2. DXA scan with T-score ≤–2.5 at lumbar spine, total hip, femoral neck, or distal radius
3. Vertebral fracture
4. eGFR <60 mL/min
5. Nephrolithiasis or nephrocalcinosis
6. Age <50 years

The ASBMR recommends parathyroidectomy for patients with 24-hour urine calcium excretion >250 mg/day for females and >300 mg/day for males, whereas the threshold delineated by the AAES is >400 mg/dL without sex stratification. The ASBMR does not recommend surgical referral for PHPT associated with impaired cognition, cardiovascular conditions, or impaired quality of life because of insufficient evidence.[16] Conversely, the AAES expands indications to include patients with neurocognitive/neuropsychiatric symptoms, cardiovascular disease, and those unwilling to comply with medical management. Our practice tracks with the ASBMR's narrower criteria, but we have noted many cases of improved quality of life with alleviation of vague symptoms after successful parathyroidectomy, and patient preference is strongly considered.

Localization

Once a firm diagnosis and a clear indication for surgery are established, the evaluation of PHPT shifts to preoperative localization. Broadly, the objective of preoperative localization is to help minimize the extent of surgical exploration and identify ectopic parathyroid(s). Localization studies have little utility in establishing a diagnosis, and rarely do they contribute to a recommendation for parathyroidectomy. Although localizing technology is constantly evolving—particularly in the realm of molecular imaging—the core modalities that are available to most surgical practices are ultrasonography, sestamibi scintigraphy, and 4D CT.

Ultrasonography is perhaps the most pervasive form of parathyroid localization and is often performed by surgeons themselves. Sonographically, a PA is typically homogeneous and hypoechoic, with well-defined borders and peripheral vascularity (Fig. 74.5). A grossly enlarged gland in a standard anatomic location is readily identified even by novice sonographers. However, small, intrathyroidal, or ectopic adenomas can be difficult to identify with confidence. Ultrasonography has the added advantage of identifying concurrent thyroid pathology, which may facilitate the treatment of multiple conditions through one surgical exploration. In experienced hands, a surgeon-performed ultrasound (SUS) can correctly localize a PA in nearly 90% of cases, and some studies have shown accuracy that exceeds sestamibi. These findings may encourage some to forego sestamibi entirely, particularly because availability of nuclear imaging could be rate limiting for surgical workup. However, it is important to recognize that ultrasonography is notoriously operator dependent, and accuracy as low as 74% has been reported.

^{99m}-Technetium sestamibi (MIBI) is absorbed by both thyroid and parathyroid via mitochondria. Within the parathyroid, oxyphil cells preferentially retain the MIBI radiotracer for a longer period than does thyroid tissue because of their greater concentration of mitochondria. In a typical MIBI protocol, images are captured immediately after tracer injection and at a 2-hour delay phase. Persistent tracer retention at the delayed phase is representative of parathyroid tissue (Fig. 74.6). Of note, thyroid nodules often retain MIBI tracer as well and can mislead interpretation. In these cases, a dual tracer protocol (i.e., 123-iodine) can facilitate a subtraction scan to better delineate between thyroid and parathyroid tissue. A standard planar MIBI scan provides very little anatomic detail, particularly along the anterior-posterior axis. Augmentation with single-photon emission computed tomography (SPECT) provides a three-dimensional correlate to the MIBI tracer. SPECT has been shown to improve sensitivity relative to MIBI, typically in the 90% to 97% range. In many facilities, SPECT can be fused with traditional computed tomography (CT) to provide further cross-sectional detail.

In 4D CT, the "fourth dimension" reflects differential enhancement over time after contrast administration. A typical 4D CT protocol includes a precontrast phase, an arterial phase, and a delay phase (60–80 s after injection). Parathyroid tissue has rapid arterial-phase uptake with rapid washout on delay phase. This allows differentiation from thyroid tissue, which has arterial

enhancement and more prolonged retention, and from cervical lymph nodes, which have minimal arterial enhancement. Pooled accuracy in a meta-analysis composed of 34 studies was 73%.[17] Compared with MIBI, 4D CT has superior anatomic detail and may facilitate localization of smaller or ectopic parathyroids. Although the overall radiation dose is similar between 4D CT and MIBI, preferential radiation to the thyroid is roughly fiftyfold higher with 4D CT than with MIBI. The clinical significance of this is debatable, however, because it translates to a lifetime absolute increase in thyroid cancer risk of 0.1% for a 20-year-old female.

In recent years, positron emission tomography with CT (PET/CT) has been adopted at some centers as another localization option for challenging cases. In a retrospective single-institution study of 84 cases, PET/CT with ^{11}C-methionine outperformed MIBI, subtraction scintigraphy, and ultrasound in sensitivity.[18] Magnetic resonance imaging (MRI) has also seen some utility for parathyroid localization. On MRI, parathyroid tissue has low- to moderate-signal on T1 and tends to have high intensity on T2. Compared with CT, MRI has advantages of avoiding ionizing radiation and intravenous contrast, but detection rates are mediocre. In general, both PET/CT and MRI are relegated to reoperative cases in which standard imaging modalities are unrevealing, all noninvasive imaging has been exhausted, and a suspected adenoma remains elusive. Selective venous sampling and selective arteriography do not provide anatomic detail but may help direct reexploration by providing general information on laterality and cervical versus mediastinal origin of PTH secretion.

Although institutional practices vary, our approach to localization begins with SUS. For patients with PTH ≥100 pg/mL and a clear single-gland adenoma on SUS, we proceed with targeted parathyroidectomy. For patients with equivocal SUS findings or PTH <100 pg/mL (for whom multigland disease or small adenomas are more likely), 4D CT is recommended. MIBI with SPECT-CT is reserved for cases in which there are discordant or negative findings on SUS and 4D CT or for suspected ectopic anatomy. If localization is unsuccessful after these three modalities have been employed, we proceed with planned four-gland exploration. PET/CT is considered for cases of reoperative disease with negative results on other imaging modalities, and selective venous sampling is used if all noninvasive modalities have been exhausted (Fig. 74.7).

Outcomes After Surgery

Because most patients with PHPT present with biochemical and DXA abnormalities rather than overt clinical symptoms, assessment of surgical outcomes requires long-term follow-up and persistent surveillance. Surgical efficacy may be measured via rate of cure and improvement or stabilization in end-organ performance. Cure from PHPT is defined as normalization of calcium and PTH at 6 months or greater after parathyroidectomy. Elevation of either marker within 6 months after surgery is considered persistent disease, whereas elevation beyond 6 months with an initial interval of normalization is considered recurrent disease. Variable rates of cure after parathyroidectomy have been reported, typically ranging from 90% to 99%. However, selection and publication bias must be considered, and it is generally accepted that there exists a volume-outcome relationship regarding efficacy of the index operation.

Surgical approach varies by institution. Minimally invasive parathyroidectomy (MIP) entails targeted removal of only the parathyroid(s) identified as abnormal on preoperative imaging, with intraoperative PTH (ioPTH) measurement to help determine adequacy of resection. Bilateral neck exploration (BNE), also called *four-gland exploration,* entails visual inspection of all four parathyroid glands with resection of those that appear grossly pathologic. Hybrid approaches involving BNE with ioPTH are a third option. In a meta-analysis of observational studies and randomized trials, no difference in cure rate was noted between BNE and MIP. BNE was associated with higher rates of postoperative hemorrhage, hypocalcemia, and recurrent laryngeal nerve injury; however, the absolute differences in risks were low. On the other hand, it is speculated that multigland disease may be an underrecognized phenomenon, and routine BNE might yield more durable normocalcemia. Further details on operative approach are included in the section on Surgical Technique.

Although achievement of normocalcemia is easy to capture via routine screening laboratory panels, definitive proof of improvement or stabilization in end-organ function is challenging. In a systematic review of randomized trials comparing surgery versus nonoperative management, parathyroidectomy provided little to no effect on bone marrow density at the lumbar spine or femoral neck, left ventricular ejection fraction, renal impairment, or all-cause mortality at 12 to 24 months follow-up.[19] However, most trials were underpowered to detect long-term sequelae because the meta-analysis included a total of only 447 participants. The review also highlighted the importance of length of follow-up. Ten-year outcomes from the Scandinavian Investigation of Primary Hyperparathyroidism randomized trial (SIPH) provided clear evidence of treatment effect from parathyroidectomy. Patients in the observation arm experienced decreases in average T-score (ΔT) at all compartments over time. Compared with these controls, the 10-year ΔT of parathyroidectomy patients was 0.41 higher at the radius and 0.58 higher at the lumbar spine. However, an absolute increase in average T-score from baseline was only noted at the lumbar spine (+0.36).[20] To summarize, there are randomized prospective data to support that parathyroidectomy provides better *preservation* of bone density compared with observation and that it *improves* bone density at the lumbar spine. Across large, population-level longitudinal cohort

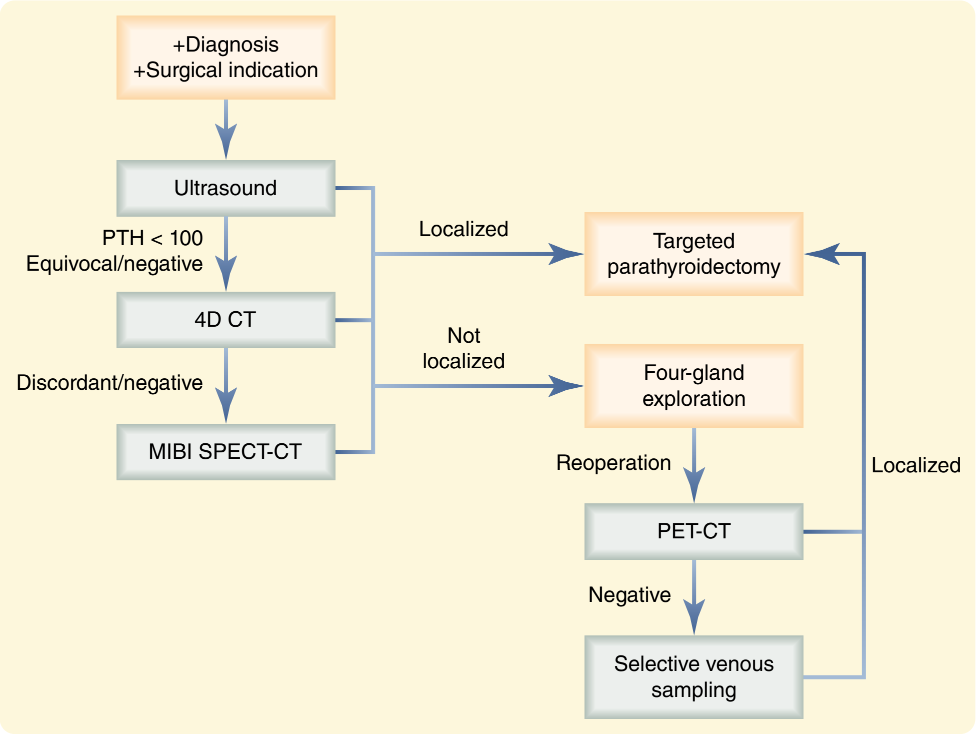

FIGURE 74.7 Approach to localization in primary hyperparathyroidism. *4D CT,* Four-dimensional computed tomography; *MIBI*, sestamibi; *PET*, positron emission tomography; *PTH*, parathyroid hormone; *SPECT*, single-photon emission computed tomography.

studies, this benefit translates to a significant reduction in long-term probability of fracture.

The effects of parathyroidectomy on extraskeletal end-organ function are less definitive. In the Medicare population, parathyroidectomy is associated with a lower incidence of major cardiovascular events and cardiovascular mortality compared with nonoperative counterparts, with an absolute risk reduction of roughly 1.5%.[21] However, randomized trials have shown no effect of parathyroidectomy on left ventricular ejection fraction at 24 months.[19] There are also scarce data to indicate that parathyroidectomy improves renal function among patients with impaired eGFR. In a retrospective study of the Danish National Patient Registry, parathyroidectomy was not associated with any change in eGFR among patients with impaired kidney function at baseline.[22] In a large target trial emulation study of a US veteran population, parathyroidectomy was associated with a reduced probability of eGFR decline compared with nonoperative management, but only in a subgroup of patients younger than 60 years of age.[23] Among patients who present with PHPT and a history of nephrolithiasis, parathyroidectomy is not associated with a reduction in future kidney stone events; however, follow-up beyond 5 years is lacking. Across three randomized trials that reported quality-of-life outcomes, two identified significant benefits over observation. However, the benefited domains differed, and a third trial found no difference between arms at 2-year follow-up.[19]

Taken together, these data may be summarized as follows: (1) There is tier 1 evidence that parathyroidectomy improves bone mineral density (BMD) compared with observation. (2) Population-level data suggest that parathyroidectomy is associated with reductions in long-term fracture risk and cardiovascular events. (3) Parathyroidectomy may be associated with a lower probability of significant eGFR decline among patients <60 years of age. For all other purported benefits of parathyroidectomy, we maintain a conservative stance during patient counseling but have observed that many patients seem to feel better after parathyroidectomy. Predicting such improvement has not been reliable, though.

Nonoperative Management

Calcium supplementation is frequently discouraged among patients with PHPT and hypercalcemia, and some physicians even recommend active restriction of dietary calcium intake. However, because of the inverse sigmoidal relationship between PTH and serum calcium, restriction of calcium intake results in minimal change in serum calcium level and may exacerbate PTH elevation. The Endocrine Society recommends *against* dietary calcium restriction and supports calcium supplementation consistent with general population guidelines (1000–1200 mg daily from all sources). Similarly, vitamin D supplementation does not worsen hypercalcemia in the setting of PHPT. Vitamin D deficiency is detrimental because the physiology of PTH regulation responds with further elevation in PTH. In a meta-analysis of retrospective studies, vitamin D supplementation was associated with lower PTH levels without worsening hypercalcemia. As such, the ASBMR recommends vitamin D supplementation on an individual basis to attain recommended normal levels of 25(OH)D3 (typically > 30 ng/mL).

The ASBMR recommends pharmacologic management of PHPT among patients who meet surgical indications but who are not appropriate surgical candidates or who are unable to achieve a surgical cure.[16] Medical management has two main objectives: preservation or improvement of BMD and reduction in hypercalcemia.

There is tier 1 evidence that bisphosphonates—most commonly alendronate—significantly improve BMD in the setting of PHPT. In one randomized, placebo-controlled crossover trial, alendronate increased BMD at the total hip, femoral neck, and lumbar spine and significantly reduced bone turnover markers. Risedronate has also been shown to increase lumbar spine BMD; however, its effects at other sites are less consistent. In a prospective observational study of postmenopausal females, parathyroidectomy outperformed a 2-year course of risedronate in tibial BMD improvement. As an antiresorptive drug class, bisphosphonates have no effect on serum calcium level, and unlike parathyroidectomy, there are no compelling data to suggest that bisphosphonates reduce long-term fracture risk.

Denosumab is another antiresorptive monoclonal antibody that acts through binding of RANKL, which in turn blocks osteoclast maturation and function. Like bisphosphonates, denosumab improves BMD and reduces bone turnover without affecting serum calcium. Although there is no randomized trial comparing denosumab to placebo in the setting of PHPT, observational data suggest that denosumab treatment is associated with reduced levels of alkaline phosphatase and an increase in BMD at the femoral neck and total hip. In one small retrospective study, patients treated with denosumab experienced comparable improvement in BMD at the lumbar spine, total hip, and femoral neck as those who underwent parathyroidectomy.

Among patients for whom correction of hypercalcemia is the primary goal of treatment, cinacalcet is the pharmacologic treatment of choice. As a calcimimetic, cinacalcet reduces serum calcium and PTH with minimal impact on BMD. In a meta-analysis of four randomized clinical trials, cinacalcet was found to significantly increase the likelihood of normocalcemia and reduce serum PTH levels compared with placebo.[24] However, there was no effect on BMD or urinary calcium. The DENOCINA trial randomized osteopenic or osteoporotic patients with PHPT to placebo, denosumab alone, or combination cinacalcet plus denosumab. BMD improved in patients who received denosumab, whereas calcium normalized in most patients who received cinacalcet.[25] Taken together, these studies suggest that bisphosphonates should be considered first-line therapy in osteoporotic patients with PHPT who cannot undergo surgery, whereas denosumab may be a second-line option. Cinacalcet may be added to correct significant hypercalcemia. Notably, no pharmacologic treatment has been shown to reduce fracture risk or cardiovascular events. Thus, patients who meet consensus indications for parathyroidectomy should be counseled that surgery is the most durable and comprehensive treatment.[16]

Hypercalcemic Crisis

Hyperparathyroidism-induced hypercalcemic crisis (HIHC) is a rare, potentially life-threatening condition that is variably reported as hyperparathyroid crisis, parathyroid storm, or parathyroid crisis. Incidence is reported as between 2% and 7% of PHPT cases and is confounded by inconsistent diagnostic criteria. A common definition is albumin-corrected serum calcium >14 mg/dL in the setting of elevated PTH and clinical symptoms. Unlike PHPT, HIHC has a female-to-male incidence ratio closer to 1:1 and mortality as high as 7%.

Among patients with PHPT, HIHC is usually precipitated by a second physiologic insult. Examples include dehydration, steroid use, surgery, thiazide diuretics, and infection. Presenting symptoms are typically neurologic and/or gastrointestinal: altered mental status, severe fatigue, anorexia, vomiting, and pain. Pancreatitis has been reported in up to 10% of cases. Cardiac signs typical of severe hypercalcemia include shortened QT interval and arrhythmia. Degree of hormonal elevation is generally more severe in HIHC than in noncrisis, and PTH in the range of 300 to 960 pg/mL is typical. Severe hypercalcemia with normal or minimally elevated PTH should prompt assessment for a second contributing etiology in addition to PHPT, such as advanced malignancy, sarcoidosis, and thyrotoxicosis.

Initial treatment of HIHC is pharmacologic correction of hypercalcemia. Most patients are hypovolemic, so intravenous normal saline is a critical first step and may be expected to drop serum calcium by roughly 2 mg/dL. After establishing euvolemia and consistent urine output, loop diuretics are introduced to reduce renal calcium resorption. Bisphosphonates inhibit bone resorption and are frequently used, but they typically do not take effect until 48 hours after initiation. Intravenous zoledronic acid is superior to pamidronate in restoring normocalcemia in malignancy and may have a faster time to onset; however, it is contraindicated in acute kidney injury. Calcitonin has rapid onset and is a useful bridge until bisphosphonates take effect. Calcitonin promotes calciuresis and can lower calcium by 1 mg/dL within 2 to 6 hours. Tachyphylaxis tends to develop within 48 hours; thus, combination therapy with bisphosphonates is recommended over calcitonin alone. For refractory cases and in patients with renal insufficiency, dialysis with a low-calcium dialysate is effective. In more recent years, other temporizing agents, such as denosumab and cinacalcet, have been described. Because of limited experience, these are generally reserved for patients for whom there is an anticipated delay in surgery.

Parathyroidectomy is recommended once the patient is medically optimized. There does not appear to be a clear advantage to expediting resection. As is the case with PHPT, most cases of HIHC are due to a single abnormal parathyroid gland, although the incidence of ectopic location and PCA are higher. As such, diagnostic workup and localization processes are largely the same for HIHC as for noncrisis cases, with ultrasound and sestamibi SPECT-CT commonly used. In surgical series, parathyroids resected for HIHC are significantly larger, and carcinoma is present in up to 10% of cases. Although the incidence of multigland disease has been reported to be as high as 24%, single-gland adenoma remains the most common culprit. Targeted parathyroidectomy guided by intraoperative PTH monitoring is reasonable (see "Surgical Technique"); however, in our practice, routine contralateral exploration is also performed because the repercussions of persistent or recurrent HIHC can be dire. In experienced hands, rates of operative success and normocalcemia at 6 months are similar between HIHC and noncrisis PHPT.

SECONDARY AND TERTIARY HYPERPARATHYROIDISM

Epidemiology

SHPT is a broad term that describes parathyroid hyperplasia and elevated PTH as an adaptive response to another physiologic insult. The two most common etiologies are vitamin D deficiency and CKD. Because isolated vitamin D deficiency is readily recognized and easily corrected, this section will focus on hyperparathyroidism because of CKD. Compensatory PTH elevation typically begins once eGFR drops to 45 mL/min. On initiation of dialysis, hyperparathyroidism is nearly ubiquitous. Persistent hyperparathyroidism with hypercalcemia—that is, tertiary hyperparathyroidism—is reported in roughly one-fifth of patients who undergo kidney transplantation.

Pathophysiology

Hyperparathyroidism develops in the setting of CKD primarily as a result of 1,25(OH)2D3 deficiency resulting from 1α-hydroxylase downregulation. Concurrent hyperphosphatemia also plays a role in upregulating PTH secretion (see Physiology). Persistently elevated PTH exacerbates renal osteodystrophy and is associated with a greater risk of osteoporosis and fracture. Histologically, parathyroids are initially characterized by polyclonal proliferation and diffuse hyperplasia. During this early phase, vitamin D and calcimimetics are effective at reducing PTH levels. Over time, there is gradual reduction in expression of vitamin D and calcium receptors on parathyroid cells, and super-physiologic secretion of PTH becomes autonomous. These changes are accompanied by evolution to nodular hyperplasia, and monoclonal adenomatous glands have also been described. This latter entity can be difficult to discern from normocalcemic PHPT.

After transplantation, early phases of SHPT are often reversible; however, advanced SHPT typically persists. In this setting, elevation of PTH with normocalcemia is generally referred to as *persistent SHPT,* whereas concurrent elevation of both PTH and serum calcium is referred to as *tertiary hyperparathyroidism* (THPT). For most patients with SHPT, serum PTH drops between 3 to 12 months after kidney transplant, with a greater likelihood of remission among patients with restored eGFR. However, roughly one in five patients evolve to long-term THPT with concurrent hypercalcemia.[26] Across retrospective datasets, THPT has been associated with delayed allograft function, higher rate of allograft failure, and higher all-cause mortality.[27] Vascular calcification and nephrocalcinosis have been proposed as potential mechanisms for this relationship; however, it remains unproven whether THPT is the instigator or the consequence of poor allograft function.

Nonoperative Management

Unlike PHPT, medical management is first line for early SHPT. The mainstays of pharmacologic treatment are vitamin D supplementation and cinacalcet. In observational studies, vitamin D supplementation in dialysis patients has been consistently associated with reduced PTH levels and improved survival. However, there is considerable risk of hypercalcemia, and consensus guidelines from the Kidney Disease Improving Global Outcomes (KDIGO) group recommend against routine supplementation in predialysis patients. Excess vitamin D may be detrimental because induced hypercalcemia and hyperphosphatemia have been linked to vascular calcification and myocardial fibrosis in animal models. With progression toward end-stage renal disease, parathyroid resistance to vitamin D develops. Although dose escalation may temporize SHPT and delay transition to nodular hyperplasia, this approach is ultimately limited by hypercalcemia and hyperphosphatemia.

Calcimimetics—most commonly cinacalcet—increase the sensitivity of parathyroid calcium receptors and increase vitamin D receptor expression. Both effects result in reduced PTH secretion and are accompanied by lower serum calcium and phosphorous. These ancillary effects on serum electrolytes make combination therapy with vitamin D appealing. Monotherapy cinacalcet has been shown to be as effective as vitamin D in lowering PTH via the PARADIGM trial.[28] The EVOLVE trial showed that cinacalcet lowered the rate of composite cardiovascular events, heart failure, and all-cause mortality compared with placebo in dialysis patients ≥65 years with severe SHPT.[29] The main drawbacks of cinacalcet are cost and incidence of nausea and vomiting in up to one-third of patients. After withdrawal of cinacalcet, calcium and

PTH tend to rebound significantly within 12 months. Currently, whether vitamin D monotherapy or combination therapy with cinacalcet is first line for SHPT remains controversial.

Surgical Indications and Outcomes

Early SHPT is typically asymptomatic, but prolonged disease may manifest with bone pain, weakness, and poor quality of life. Persistent hypercalcemia, hypophosphatemia, and anemia are common. Unlike PHPT, there is no consensus set of criteria for surgical referral. Most centers recommend surgery for SHPT or THPT that is symptomatic or has persistent electrolyte derangements despite maximal medical management. Degree of PTH elevation is a consideration: KDIGO recommends maintaining PTH at two to nine times the normal range (upper limit ≤585 pg/mL), but target thresholds of ≤500 or ≤800 have also been cited. In large retrospective series, patients with SHPT or THPT who undergo parathyroidectomy experience a significant increase in BMD and a lower risk of hip fracture.[30] Patients who undergo parathyroidectomy for SHPT while on dialysis tend to have durable treatment effect after subsequent transplant, with lower rates of developing THPT and need for posttransplant cinacalcet.[31] However, less than 5% of transplanted patients undergo parathyroidectomy for SHPT in the pretransplant setting.[32]

There is persistent debate regarding the indications for and timing of parathyroidectomy for THPT. Iatrogenic hypercalcemia due to vitamin D and/or cinacalcet in the SHPT setting typically improves within a month after transplantation once these drugs are stopped. However, a delayed phase of recurrent hypercalcemia is commonly noted roughly 6 months thereafter. In part because of these fluctuations over the first year, consideration of parathyroidectomy is typically deferred until 9 to 12 months after transplantation. Because persistent use of vitamin D supplementation or its analogs after kidney transplantation is limited by hypercalcemia, treatment options for THPT are predominantly cinacalcet or parathyroidectomy. In one retrospective series, early referral to parathyroidectomy (<278 days) was associated with improved preservation of posttransplant kidney function.[33] Despite the deleterious relationship between THPT and allograft function, there is no consistent evidence that parathyroidectomy improves long-term allograft survival. In a small randomized trial comparing parathyroidectomy versus cinacalcet, there was no difference between groups in rate of normocalcemia, PTH level, BMD, or creatinine.[34] Nevertheless, acknowledging low-quality evidence, the AAES supports parathyroidectomy as the treatment of choice for THPT and recommends surgical referral within 12 months posttransplant should patients experience persistent hypercalcemia.[35] Retrospective series have shown that parathyroidectomy for THPT may result in a transient reduction in eGFR by approximately 25%.[26] However, in most studies, allograft function recuperates to at least preparathyroidectomy levels by approximately 1 year, suggesting that this detriment is secondary to hemodynamic shifts during surgery rather than a durable pathophysiologic effect.

Choice of Surgery

The most common operations performed for SHPT and THPT are SPTX and total parathyroidectomy with autotransplantation (PTX-AT). In a small, randomized trial, PTX-AT outperformed SPTX in calcium normalization and clinical symptoms. PTX-AT has the added advantage that delayed reoperation to excise additional parathyroid tissue, if necessary, is less complex in the forearm than in a reoperative cervical field. However, data from the National Surgical Quality Improvement Program show that PTX-AT is associated with longer operating time and length of stay. In a meta-analysis of 18 studies and over 3500 patients, there was no difference between techniques in symptomatic improvement, persistent disease, recurrence rate, or reoperation. Persistent disease was present in 6% of SPTX patients and 2% of PTX-AT, and rates of reoperation were 5.3% and 5.8%, respectively. PTX-AT was associated with longer operating time and length of stay and a higher rate of long-term vitamin D supplementation.[36] Taken together, these data suggest that SPTX and PTX-AT are both highly effective at treating THPT, with PTX-AT trading more prolonged recovery for slightly increased short-term efficacy. The AAES recommends SPTX as the preferred option for patients with enlargement of all four parathyroids but acknowledges surgeon preference remains a key contributor.[35] Further details on surgical principles are available in the Surgical Technique section.

Postoperative Management

Regardless of surgical approach, recovery after parathyroidectomy for SHPT and THPT is more complex than for PHPT. This translates to longer length of stay and higher complication and readmission rates. Hungry bone syndrome (HBS) is a common phenomenon after SPTX and PTX-AT. It is reported in roughly 13% of patients undergoing parathyroidectomy for PHPT and up to 50% of patients undergoing surgery for SHPT or THPT.[37,38] Risk of HBS is lower for THPT than for SHPT and lower for SPTX than for PTX-AT.[35] Nearly all patients experience transient hypocalcemia after TPX-AT. HBS is defined as hypocalcemia for >4 days after surgery and is secondary to unchecked osteoblastic calcium uptake accompanying the dramatic decrease in serum PTH that follows parathyroidectomy. If uncorrected, symptoms include paresthesia, perioral numbness, and muscle locking, whereas severe disease can result in arrhythmia, tetany, and seizures.

Anticipation and prompt management of HBS are key to efficient postoperative recovery. Most centers employ immediate postoperative oral calcium carbonate and calcitriol, and some implement these medications preemptively before surgery for up to 1 week. Hypocalcemia refractory to oral supplementation is treated with intravenous calcium gluconate. Typically, native calcium levels nadir at between 2 and 3 days after surgery, after which intravenous calcium may be transitioned gradually to an oral regimen. Hypomagnesemia and hypophosphatemia are common accompaniments as a result of bone deposition, and these require vigilant supplementation. Rates of persistent hypocalcemia and hypoparathyroidism are not often reported but may be in the 5% to 20% range, depending on choice of operation and duration of vitamin D supplementation.[39,40]

Calciphylaxis

Calciphylaxis, also referred to *as calcific uremic arteriolopathy,* is a highly morbid condition usually reported among dialysis patients, although it can also afflict those in earlier stages of CKD. Nonuremic calciphylaxis is also described but is rare. First described by Hans Selye via a series of animal experiments, the condition became recognized in human subjects in 1969. Clinically, the disease presents with ischemic, painful, persistent skin wounds that progress to ulceration and infection (Fig. 74.8). Ischemia of muscle, viscera, and eyes have also been described. Pathogenesis is thought to be via small vessel calcification, and histologic inspection of skin biopsies often shows microthrombosis and fibrointimal hyperplasia. However, because of its rarity, most human data take the form of case series and case-control studies, and its mechanism remains under investigation.

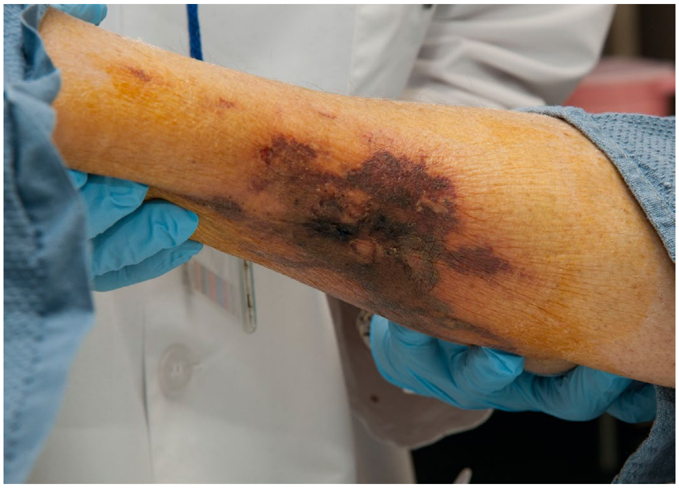

FIGURE 74.8 A violaceous skin lesion with ischemia and eschar formation resulting from calciphylaxis.

Risk factors for calciphylaxis vary across reports. Dysregulation of calcium and phosphorous due to abnormal mineral bone metabolism is thought to contribute to small vessel deposition and is compounded by iatrogenic effects from vitamin D or its analogs. However, calciphylaxis is not exclusive to patients with severe hypercalcemia or those with very elevated PTH. Other proposed risk factors include female sex, autoimmune disease, hypercoagulability, obesity, and medications that increase serum calcium. The relationship between warfarin and calciphylaxis is particularly notable. Although its intended therapeutic action is repression of vitamin K–dependent coagulation factors, it also affects vitamin K–dependent factors that inhibit vascular calcification, such as matrix Gla protein, thereby inducing vascular calcification in animal models. The relationship in humans is not fully understood, however, and tissue ischemia in patients who recently started warfarin must also raise consideration of warfarin-induced necrosis.

Because risk factors are inconsistent and clinical presentation varies widely, confirming a diagnosis of calciphylaxis can be challenging. There is no laboratory marker that establishes calciphylaxis, but a thorough workup for comorbid and contributing conditions should include a liver panel, bone turnover markers, hypercoagulation panel, and evaluation for autoimmune disease. Sequelae of calciphylaxis, such as local infection and sepsis, must be assessed continuously because these are the most common pathways to mortality. A punch or incisional biopsy that includes the edge of a suspected calciphylactic lesion and adjacent normal skin establishes the diagnosis. Histologic signs include calcification, thrombosis, and fibrointimal hyperplasia of arterioles, along with septal panniculitis.

Treatment of calciphylaxis is supportive and multidisciplinary. Wound care is paramount, with chemical debridement of small, noninfected ischemic ulcerations and surgical debridement of larger or infected areas of necrotic tissue. Surgical strategies include serial debridement with negative-pressure appliances, skin grafts, and hyperbaric oxygen, although no one protocol is supported by high-level evidence. Pain control is multimodal and adjusted for renal clearance. Cinacalcet, sodium thiosulfate, and phosphate binders are used to control serum PTH, and vitamin D and its analogs should be discontinued or used very judiciously. The Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) trial comparing cinacalcet to placebo noted a threefold lower rate of calciphylaxis in the cinacalcet arm.[41] The role of parathyroidectomy in calciphylaxis is controversial. Although some recommend early resection, an alternative approach is to restrict surgery for refractory cases with PTH $>$ 300 ng/mL despite cinacalcet. If parathyroidectomy is indicated, SPTX or PTX-AT is preferred over more limited resections to avoid persistent or recurrent disease.

PARATHYROID CARCINOMA

Epidemiology

PCA is among the rarest solid organ malignancies in humans, accounting for less than 1% of PHPT. Because of its rarity, robust data on risk factors and even diagnostic criteria are lacking. A history of neck irradiation, younger age at diagnosis, and advanced kidney disease have been linked to PCA, but the condition remains rare in all patient strata. Most cases are sporadic, but both germline and somatic mutations have been characterized as pathogenic in a subset of cases. These included inherited mutations in *CDC73* (HPT-JT), *MEN1* (MEN1), *RET* (MEN2A), *TP53,* and *PRUNE2* as well as down- and upregulation via abnormal DNA methylation.

Diagnosis and Imaging

Preoperative diagnosis of PCA is rarely conclusive, and most cases of PCA are established after index resection, either on pathologic assessment or delayed recurrence at locoregional or distant sites. In fact, the criteria to establish a pathologic diagnosis of PCA have been debated over recent years. Current histologic features that confirm PCA, according to the WHO, are any of the following: (1) angioinvasion, (2) lymphatic invasion, (3) perineural invasion, (4) invasion into surrounding structures, or (5) confirmed metastatic disease.[42] It has been proposed that classic PA and PCA fall on a histologic spectrum, without a clear delineation. As such, borderline cases that feature nuclear pleomorphism, increased mitotic activity, necrosis, fibrotic bands, Ki-67 $>$5%, or pseudocapsular invasion without clear malignant criteria are collectively classified as "atypical parathyroid tumors."[43] The nomenclature has changed from prior WHO renditions, in which it was called *atypical parathyroid adenoma.* This reflects the acknowledgment that metachronous recurrence (local or distant) has been reported in roughly 3% of atypical cases.

Preoperative evaluation for PCA requires a high index of suspicion. Unlike PHPT, PCA tends to present with severely elevated serum calcium, often $>$3 mg/dL above the upper limit of normal. PTH levels are similarly elevated to greater than threefold the normal range, and values 10 times the normal range have been reported. Alkaline phosphatase elevation $>$300 IU/L may be indicative of high bone turnover associated with PCA, but this is not a sensitive threshold. Although most cases of PHPT are recognized incidentally on laboratory testing, PCA has a higher rate of end-organ complications. Presenting symptoms include nephrolithiasis, renal insufficiency, pathologic fracture, osteitis fibrosa cystica, and hypercalcemic crisis. Symptoms from mass effect and local invasion may be present, including dysphagia, compression, palpable mass, and vocal cord palsy. These latter findings are more commonly noted in nonfunctioning PCA—which constitutes roughly 10% of cases—and portend a worse prognosis as a result of delay in diagnosis.

Noninvasive imaging plays an important role in diagnosis, staging, and surgical planning. Sonographic features that may differentiate PCA from benign adenoma include size $>$3 cm, ill-defined margins, heterogeneity, invasion of surrounding structures, adenopathy, calcification, and greater depth-to-width ratio. However, no one feature is pathognomonic, and with the exception of regional invasion, all may be found in benign or atypical cases. Sestamibi, with or without SPECT-CT, serves not only to localize the primary tumor but also can demonstrate metastatic lesions as well. Cross-sectional anatomy is best evaluated via 4D CT or MRI and should be performed preoperatively for patients who have a biochemical and clinical presentation that places them at high risk for PCA. When performed, CT is extended to include the chest and abdomen to assess for metastatic disease. Routine positron emission tomography is not indicated for staging but may be effective for suspected recurrence or in cases of nonfunctioning PCA that are not sestamibi avid.

Needle biopsy or aspiration is not recommended because tract site tumor implants have been reported. Moreover, aspirated specimens are frequently ineffective at differentiating between benign adenoma and atypical tumors, and they do not address any of the criteria for confirming PCA. However, needle aspiration may have a role in establishing a diagnosis of metachronous metastatic recurrence, particularly among patients with a suspicious distant lesion that is not sestamibi avid. In such cases, fine-needle aspiration with PTH washout may be diagnostic.

Treatment

Initial treatment of suspected PCA focuses on managing signs and symptoms of hypercalcemia. Patients presenting in hypercalcemic crisis should be temporized pharmacologically (see “Hyperparathyroid-Induced Hypercalcemic Crisis”). Once the patient is stabilized, imaging is obtained to localize the offending parathyroid and assess for locoregional and distant extent of disease.

The only curative treatment for PCA is resection based on oncologic principles. Margin positivity is associated with significantly worse overall survival; thus, en bloc resection of the ipsilateral thyroid lobe is recommended because the parathyroid is often adherent to the adjacent thyroid. Most cases of PCA are not recognized preoperatively and are instead diagnosed on pathology after resection for presumed benign PHPT. In fact, less than 15% of cases undergo en bloc resection, and incomplete resection is reported in up to two-thirds of cases. After index surgery, if calcium and PTH remain elevated and pathologic inspection reveals positive margin(s), reoperation after interval imaging is advised. On the other hand, for patients with normalization of calcium and PTH in the setting of an R1 resection, the incremental benefit of reexploration may not justify the accompanying elevated risk of nerve injury.

There are no robust data on adjuvant therapy. PCA is resistant to radiation, and its role in locoregional control should be restricted to margin-positive or recurrent cases that are not amenable to reoperation. There is no role for adjuvant chemotherapy in PCA. Systemic therapy for recurrent disease is relegated to cases for which metastatic lesions are not amenable to surgery and hypercalcemia progresses despite maximal treatment with appropriate agents. In these very rare instances, case reports have documented efficacy of temozolomide, mammalian target of rapamycin (mTOR) inhibitors, and antiangiogenic tyrosine kinase inhibitors. In most cases, response is assessed not via traditional radiographic criteria but by improvement in severity of hypercalcemia.

Outcomes After Surgery

PCA is currently staged via the American Joint Committee on Cancer (AJCC) 8th edition classification scheme. T1 is localized to the parathyroid, T2 entails invasion into adjacent thyroid, T3 indicates invasion into other surrounding structures, and T4 describes invasion into major blood vessels (i.e., carotid, subclavian) or spine. N1a describes nodal metastases in levels VI or VII of the central neck, whereas N1b indicates involvement of stations I through V or retropharyngeal nodes. Distant metastases are classified as M1.[44] Because of disease rarity, prognostic stratification by risk factors is challenging. Larger tumor diameter and incomplete resection are associated with worse survival, but there is no consistent relationship between N1 disease and mortality. As such, routine central neck dissection does not serve a clear therapeutic or prognostic role.

Overall, PCA is a relatively indolent cancer. Five-year survival is estimated at 85% to 91%, whereas 10-year survival ranges from 50% to 85%.[45] However, recurrence is common, estimated in some series to be over 50%, with locoregional recurrence outnumbering metachronous metastases. Electrolyte derangements and recurrent hyperparathyroidism are indicative of recurrence, and long-term morbidity is driven by persistent PHPT rather than local effects. Re-resection of local recurrence and/or metastasectomy are aimed at attaining disease control and palliation of endocrinopathy. Multiple palliative operations may be performed for a single patient. Normalization of PTH and calcium via noncurative resection can have a durable impact on both survival and quality of life.

HEREDITARY HYPERPARATHYROIDISM

Most cases of PHPT are sporadic, whereas less than 5% of cases harbor a heritable mutation. Among these, most are attributable to genes well known to confer PHPT—sometimes in isolation, more commonly as one entity within a syndrome of other disorders. Understanding associated diseases directly affects management and surveillance, whereas identifying the genetic culprits holds implications for prognosis and screening of family members. There is no single consensus guideline for genetic testing in PHPT. It is commonly recommended to consider germline testing for patients with two affected primary relatives, anyone with PCA, those with recurrent PHPT, and patients <40 years of age.[46] A summary of genetic abnormalities found in sporadic and heritable hyperparathyroidism is provided in Table 74.1.

Multiple Endocrine Neoplasia Type 1

The *MEN1* gene was first identified in 1997, but cases that likely reflect MEN1 have been documented as early as 1927 by Harvey Cushing, who recorded a patient with a pancreatic islet cell tumor, PHPT, and acromegaly. The syndrome’s autosomal dominant pattern of inheritance was described by Paul Wermer in the 1950s, hence its initial eponym *Wermer syndrome. MEN1*’s corresponding protein, menin, has diverse roles in transcription modulation, DNA repair, cell signaling, and mitosis. MEN1 is characterized by multigland parathyroid hyperplasia, pancreatic neuroendocrine tumors (NETs), and pituitary adenomas. There is close to 100% penetrance of PHPT by the fifth decade. Disease onset is earlier than in sporadic cases, with biochemical derangements noted in childhood or adolescence and symptomatic presentation typically in the third decade. PHPT due to MEN1 tends to have more end-organ effects than sporadic cases, with lower BMD and higher rates of nephrolithiasis and CKD.[47]

Associated conditions include anterior pituitary adenomas, which most frequently secrete prolactin or somatotropin but may also be nonfunctional. Gastropancreatic NETs are often the most

TABLE 74.1 Genetic Abnormalities Associated With Sporadic and Inherited Forms of Primary HPT: Disorder, Genes, Inheritance, Phenotype, and Recommended Surgical Approach

DISORDER	GENES	INHERITANCE	PHENOTYPE	AGE[a]	SURGICAL APPROACH[b]
Sporadic					
Parathyroid adenoma and hyperplasia	*PRAD1, CCND1* (20%–40%), *MEN1* (12%–35%), *CDC73, CDKN1B, AIP*	Sporadic	Isolated pHPT with single adenoma, double adenoma, or four-gland hyperplasia	>45	Minimally invasive parathyroidectomy with ioPTH or bilateral exploration
Parathyroid carcinoma	*RB1, CDC73, MEN1, microRNA-296*	Sporadic	pHPT secondary to parathyroid carcinoma	>45	En bloc resection
Inherited					
MEN1	*MEN1*	AD	pHPT (95%) in third decade, pNETs (40%), pituitary adenomas (30%), adrenocortical and thyroid tumors, meningioma, facial angiofibromas, lipomas	25–45	Subtotal parathyroidectomy and transcervical thymectomy
MEN2A	*RET*	AD	pHPT (15%–35%), MTC (99%), pheochromocytoma (50%), lichen planus, amyloidosis, Hirschsprung disease	38	Resection of only visibly enlarged parathyroid glands. Address or rule out pheochromocytoma first
MEN4	*CDKN1B*	AD	pHPT (80%), pituitary adenoma (40%), pNETs, adrenal, thyroid, gonadal and renal tumors	50	Same as MEN1
Familial isolated HPT	*MEN1, CDC73, CASR, GCM2, CDKN1B*	AD	Isolated pHPT, parathyroid carcinoma (*GCM2* mutation)	39	Bilateral neck exploration with resection of enlarged glands only versus subtotal parathyroidectomy En bloc resection for parathyroid cancer
HPT-JT	*CDC73*	AD	pHPT in second or third decade, parathyroid carcinoma (35%), ossifying fibromas of mandible and maxilla, renal cysts, hamartomas and Wilms tumor, uterine tumors	32	Minimally invasive parathyroidectomy with ioPTH or bilateral exploration En bloc resection for parathyroid cancer

[a] Age = mean age at presentation of primary HPT in years.

[b] Surgical approach to HPT associated with the disorder.

life-limiting component of MEN1 and affect up to 80% of patients. Gastrinomas of the pancreatic head or second portion of the duodenum—the so-called "gastrinoma triangle"—are most common. Gastrin excess leads to hypersecretion of gastric acid and multiple recurrent ulcers of the stomach and duodenum, that is, Zollinger-Ellison syndrome. Other hormone products include insulin, vasoactive intestinal peptide, and glucagon, each with its own pathognomonic clinical signs. Other conditions linked to MEN1 include lung NETs, breast cancer, and thymic NETs. Most NETs within the MEN1 spectrum are either indolent (lung, breast, pituitary) or have variable malignant behavior (pancreatic NETs) and are manageable via resection and pharmacologic control of systemic effects. However, thymic NETs are increasingly recognized for their unusually aggressive natural history. Despite being prevalent in 2% to 8% of MEN1 patients, they are responsible for 20% of deaths, and most cases present with metastatic disease.[47]

The traditional surgical management of MEN1 PHPT is SPTX with cervical thymectomy. The philosophy is similar to management of SHPT, focusing on establishing durable control without inducing long-term hypocalcemia. However, it is increasingly recognized that hyperplasia in the setting of MEN1 is often asynchronous, and subtotal parathyroidectomy (or PTX-AT) in children or adolescents may induce prolonged hypoparathyroidism during an important phase of bone deposition. In recent years, reports of less-than-subtotal parathyroidectomy have gained traction. This approach is usually guided by 4D CT or parathyroid venous sampling to direct resection to the side of the neck with more dominant hyperplasia. Single-institution cohorts have shown that unilateral parathyroidectomy and thymectomy may produce durable control of PHPT with negligible risk of prolonged hypoparathyroidism.[48]

Multiple Endocrine Neoplasia Type 2a

The first patient with the grouping of medullary thyroid cancer, pheochromocytoma, and parathyroid enlargement was described by John Sipple in 1961, hence the name *Sipple syndrome.* Other associated features include cutaneous lichen amyloidosis. Pattern of inheritance is autosomal dominant, via activating mutations in the *RET* receptor tyrosine kinase proto-oncogene. The most common affected codons are 634 (85%), 609, and 618.[49] *RET* mutations are also associated with MEN2B and familial medullary thyroid cancer, but these are not affiliated with PHPT.

PHPT is a feature of 20% to 30% of cases of MEN2A and is most frequent among cases with a codon 634 mutation. Conversely, medullary thyroid cancer is nearly 100% penetrant. Thus, surgical treatment of PHPT is technically challenging because most patients have previously undergone total thyroidectomy by the time PHPT manifests. Unlike MEN1 and most other heritable PHPTs, MEN2A is typically characterized by one or more benign PA(s) rather than diffuse hyperplasia of all four glands. The surgical approach, therefore, leans more toward the philosophy of sporadic PHPT rather than that of MEN1 or SHPT/THPT. Although practice patterns vary, one common approach is preoperative localization followed by four-gland exploration with resection of any parathyroid(s) that appear hyperplastic. Similarly, if one or more enlarged parathyroids are encountered at the time of total thyroidectomy in the setting of known MEN2A, empiric parathyroidectomy should be performed.

Multiple Endocrine Neoplasia Type 4

Germline mutation in *CDKN1B,* which encodes the cyclin-dependent kinase inhibitor p27, is associated with acromegaly and PHPT. This disorder was first described in 2006 in both humans and rat models and has phenotypic overlaps with MEN1. In 2019, a multigenerational Danish family was reported that included members with PHPT who segregated with mutations in *CDKN1B*. Like MEN1, MEN4 presents with diffuse parathyroid hyperplasia and pituitary adenomas. Uniquely, however, MEN4 is also linked to testicular and cervical cancer and adrenal Cushing disease.[50] The surgical treatment of choice is SPTX or PTX-AT.

Hyperparathyroidism–Jaw Tumor Syndrome

Although advanced PHPT can result in giant cell bone lesions as a component of osteitis fibrosa cystica in <5% of cases (i.e., "brown tumors"), ossifying fibromas isolated to the maxilla and/or mandible are indicative of HPT-JT. These lesions lack the multinucleated giant cells characteristic of brown tumors. HPT-JT was first described in 1990 and is inherited in an autosomal dominant fashion. The genetic culprit is inactivation of *CDC73,* which encodes the parafibromin tumor suppressor protein.

Associated features include mixed epithelial and stromal tumors of the kidney, renal cysts, and Wilms tumor. Uterine soft tissue tumors, including leiomyomas and adenosarcomas, have also been linked to HPT-JT. Unlike MEN1 and MEN2A, HPT-JT is associated with an elevated risk of PCA, affecting one in five patients.[49] Risk of malignancy is even higher among patients with a frameshift or deletion mutation of *CDC73,* which is also commonly identified as a somatic mutation in isolated PCA. Like MEN2A, HPT-JT is typically characterized by single-gland parathyroid disease. Thus, focused parathyroidectomy guided by preoperative localization is appropriate. Because of the predisposition for PCA, a low threshold for en bloc ipsilateral thyroidectomy should be considered for cases in which the abnormal parathyroid is firm, adherent to the thyroid, or intracapsular.

Familial Isolated Hyperparathyroidism

For patients with a family history of PHPT suggestive of autosomal dominant inheritance who do not fit into one of the previously described syndromes based on genetic testing or phenotype, FIHP may be considered as a provisional diagnosis of exclusion. Over the last 20 years, as features of HPT-JT and MEN4 have become more thoroughly described, some patients originally classified as FIHP have been reassigned. Many cases of presumed FIHP lack germline mutation of any known PHPT pathway genes. Both *MEN1* and *CDC73* have been implicated, but these cases may represent MEN1 or HPT-JT with incomplete penetrance. Several studies have identified *GCM2* in a subset of FIHP. *GCM2* encodes a transcription factor expressed in chief cells, and activating mutations of the inhibitory domain are thought to result in FIHP. Because the parathyroid phenotype of FIHP varies greatly depending on genotype, routine bilateral exploration with either SPTX or resection only of grossly abnormal glands—guided by intraoperative PTH (ioPTH)—is reasonable.

SURGICAL TECHNIQUE

For most experienced surgeons, resecting a well-localized PA within a standard cervical location is a straightforward operation. However, challenges arise when multigland disease, supernumerary glands, and ectopic locations come into play. Intraoperative technologies have been directed at assisting in the identification of parathyroid tissue, but none supplants operative experience, anatomic familiarity, and meticulous dissection. Careful respect of embryologic tissue planes is critical because bleeding within the surgical field quickly obscures the delineation of parathyroid from surrounding tissues. Once the gland is identified, dissection is focused on avoidance of capsular disruption, which can lead to parathyromatosis and the need for additional, higher-risk operations. In the context of BNE, exposure of parathyroids that are anticipated to be normal requires close attention to native vasculature because compromise of the feeding pedicle can cause temporary or even permanent hypoparathyroidism. Although novel surgical approaches such as transaxillary and transoral endoscopic or robotic parathyroidectomy have given options to patients who wish to avoid a cervical incision, core surgical principles have not changed.

The superior parathyroid glands are classically located posterior to the superior thyroid poles, posterior and lateral to the trajectory of the recurrent laryngeal nerve bilaterally (Fig. 74.9). Their positions are relatively predictable compared with the more variable anatomy of the lower glands and are typically close to the intersection between the middle thyroid vein and the recurrent laryngeal nerve. The inferior parathyroid glands are usually located inferior and posterior to the lower poles, medial to the recurrent laryngeal nerves, along the tracheoesophageal groove. The four glands, in sequence of average proximity to the nerve, are right upper (closest), followed by left upper, left lower, and right lower.

Ectopic parathyroids are reported in up to 16% of cases. The most common scenario is of an ectopic lower parathyroid within the cervical or superior mediastinal thymus (Fig. 74.10). It is for this reason that a cervical thymectomy is commonly performed accompanying SPTX or PTX-AT or for cases in which ioPTH fails to respond appropriately despite BNE. Other common ectopic positions include the carotid sheath, superiorly along the superior thyroid pole vessels, retroesophageal, and retropharyngeal. Parathyroid glands uncommonly may be found under the thyroid capsule or even within the thyroid gland itself. This has led to the practice of ipsilateral thyroid lobectomy if a gland cannot be found. We uncommonly perform blind thyroid lobectomy and favor ultrasound or bivalving the thyroid lobe, especially if an internal jugular PTH gradient of 10% is demonstrated. Thorough

exploration of each of these positions—within the constraints of the cervical incision—is indicated for inadequate ioPTH response (Fig. 74.11).

Intraoperative measurement of PTH level is a requisite component of MIP and is frequently used in BNE as well. Because the systemic half-life of PTH is between 3 and 5 minutes in most patients, ioPTH is typically measured before excision of the abnormal parathyroid gland and at 5- and 10-minutes after excision. Because manipulation of the hyperplastic or adenomatous gland may result in a brief spike in PTH secretion, preoperative levels are typically drawn at both induction of general anesthesia and immediately before ligation of the parathyroid vascular pedicle. When ioPTH is used, successful surgery is defined by the Vienna criteria (reduction in ioPTH by at least 50% within 10 minutes of excision compared with highest preexcision baseline) or the Miami criteria (satisfaction of Vienna criteria plus normalization of ioPTH). Rigorous adherence to these criteria has reduced the rate of persistent PHPT after surgery to <5% in most large series.

The vagus nerve is retracted with a vessel loop anteromedially, and the common carotid artery is retracted laterally. (B) Ex vivo ectopic parathyroid adenoma excised from the left carotid sheath.

SPTX describes planned resection of three parathyroid glands with partial resection of the fourth gland. Typical technique involves BNE with identification of all four glands and assigning the smallest gland for the planned remnant. A portion of that gland is excised, leaving a 40- to 80-mg remnant (roughly one to two times the size of a normal gland) with an intact vascular pedicle. Viability of the remnant can be assessed using visual inspection of color and bleeding at the cut edge. The remaining three glands are then excised after marking the location of the in situ remnant with permanent suture for future identification in the setting of recurrence. With PTX-AT, all four glands are excised, and a portion of one gland is morcellated sharply into <1-mm sections, then aspirated in 1 mL of normal saline. The mixture is then immediately injected into muscle—typically the brachioradialis or sternocleidomastoid—either percutaneously or via cut-down. If direct exposure is obtained, development of a pocket within well-vascularized muscle with meticulous hemostasis is encouraged because surrounding hematoma will compromise incorporation of the implant.

The challenge of accurately identifying and preserving parathyroids and their vasculature during operative exploration has led to advancements in intraoperative parathyroid imaging. The most common techniques harness intrinsic or extrinsic fluorophores to locate tissue using near-infrared fluorescence detectors. Parathyroid tissue emits autofluorescence at 820 nm when excited with a near-infrared laser. This forms the basis of probe-based detector systems, which house both a near-infrared laser and a photodiode detector. The system has been shown to detect parathyroid tissue with sensitivity and accuracy exceeding 90%.[51] However, successful localization of parathyroid tissue does not imply preserved blood flow. For this, intravenous injection of indocyanine green (ICG) may be used in conjunction with perfusion angiography to generate an intraoperative map of both the parathyroid gland and its contributing vascular pedicle. An important limitation of these technologies is the depth of near-infrared light penetration within tissue, which is limited to approximately 5 mm. Thus, both techniques are primarily used to confirm the presence of parathyroid after the presumed gland has already been fully exposed. As such, implementation is more relevant to avoidance of inadvertent parathyroid excision or devascularization in the context of thyroidectomy rather than initial localization during planned parathyroidectomy.

Complications after parathyroidectomy are rare when performed by experienced surgeons. Knowledge of these risks can guide safe postoperative management. Transient hypocalcemia occurs in 1.6% of MIP and up to 13.2% of BNE, and permanent hypocalcemia occurs in less than 0.2% of cases. Thus, single-gland excisions in the context of MIP do not require postoperative calcium assessment or supplementation, although some surgeons take an individualized approach to postoperative calcium supplementation after BNE. In the context of SHPT or THPT, subtotal or total parathyroidectomy is associated with a significantly elevated risk of temporary hypocalcemia. Temporary vocal cord palsy occurs in <1% of cases and is not consistently different by approach across studies. Although permanent vocal cord palsy is higher with BNE in several studies, the absolute risk is <0.2%. Although intraoperative neuromonitoring of the recurrent laryngeal nerve is widely used, there is no prospective evidence proving its efficacy in reducing the rate of nerve injury in parathyroidectomy. Postoperative hemorrhage is reported in <1% of BNE and <0.5% of MIP; nevertheless, its occurrence may be life threatening. Therefore, although most parathyroidectomies may be performed on an outpatient basis, an observation period of 4 to 6 hours after surgery is recommended.

HISTORY

The adrenal glands were first described by the Italian anatomist Bartolomeo Eustachi in 1564 as "glandulae quae renibus incumbent," or "glands lying on the kidney." The German comparative anatomist Albert von Kölliker (1817–1905), who noted the presence of the adrenals in a number of vertebrate species, is credited with first identifying two distinct portions of the adrenal gland: the cortex and the medulla. Although Thomas Addison described the clinical features of primary adrenal failure in 1855, it was not until nearly a century later that the adrenal hormones were fully isolated and characterized. Adrenaline (or epinephrine) was first isolated from adrenal extract at the turn of the century circa 1900. Steroid hormones were crystallized from cortical extract ("cortin") by Swiss and American investigators in the 1930s, but their highly similar chemical structures made isolation of the individual compounds challenging. Edward Kendall, Tadeus Reichstein, and Philip Hench jointly received the 1950 Nobel Prize in Physiology or Medicine for their groundbreaking work on the adrenocortical hormones. The Austrian-born endocrinologist Hans Selye first described the stress response in mammals in 1936 and made major contributions to the understanding of the hypothalamic-pituitary-adrenal (HPA) axis. Roger Guillemin, Andrew Schally, and Rosalyn Yalow were awarded the Nobel Prize in 1977 for characterizing the peptide hormones of the brain that underlie the HPA axis as we now understand it.[1,2]

ANATOMY AND EMBRYOLOGY

General and Developmental Aspects

The adrenal glands are paired, orange/yellow-colored structures that are positioned superior and slightly medial to the kidneys in the retroperitoneal space (Fig. 75.1). They are flattened and roughly pyramidal or crescent shaped, weighing approximately 4 g each. The adrenals are among the most highly perfused organs in the body, receiving 2000 mL/kg/min of blood, after only the kidney and thyroid. In most respects, the cortex and medulla can be considered two completely distinct organs that happen to colocalize during development. The two portions have disparate embryologic origins. The primordial cortex arises from the coelomic mesodermal tissue near the cephalic end of the mesonephros during the fourth to fifth week of gestation. Biosynthetic activity can be detected as early as the seventh week. Cortical cell mass dominates the fetal adrenal at 4 months of development, and steroidogenesis is maximum during the third trimester. The adrenal medulla arises from the ectodermal tissues of the embryonic neural crest. It develops in parallel with the sympathetic nervous system, beginning in the fifth to sixth week of gestation. From their original position adjacent to the neural tube, neural crest cells migrate ventrally to assume a paraaortic position near the developing adrenal cortex. There, they differentiate into chromaffin cells that make up the adrenal medulla.

This course of embryologic development yields certain surgically relevant sequelae. Both cortical and medullary tissue can be found at extraadrenal sites (Fig. 75.2). The range of potential sites is wider for chromaffin tissue than for cortical tissue. Pheochromocytomas may arise in extraadrenal sites more commonly than previously believed. When they are extraadrenal, pheochromocytomas are also termed *paragangliomas*.

Relationships

The right adrenal gland abuts the posterolateral surface of the retrohepatic vena cava. The right adrenal fossa is bounded by the right kidney inferolaterally, diaphragm posteriorly, and bare area of the liver anterosuperiorly. The left adrenal gland lies between the left kidney and aorta, with its inferior limb extending farther caudad toward the renal hilum than the right adrenal. The other relationships of the left adrenal gland are the diaphragm posteriorly and the tail of the pancreas and splenic hilum anteriorly. Each adrenal gland is enveloped by its proper capsule, in addition to sharing Gerota's fascia with the kidneys. The adrenal capsules are immediately associated with the perirenal fat.

Vasculature

Knowledge of the macroscopic vascular anatomy of the adrenal glands is essential to proper surgical management. It is important to conceptualize that although the arterial supply is *diffuse,* the

venous drainage of each gland is usually *solitary*. The arterial supply arises from three distinct vessels—superior adrenal arteries from the inferior phrenic arteries, small middle adrenal arteries from the juxtaceliac aorta, and inferior adrenal arteries from the renal arteries. Of these, the inferior is the most prominent and is commonly a single identifiable vessel. The left adrenal vein is approximately 2 cm long and drains into the left renal vein after joining the inferior phrenic vein.[3] The right adrenal vein is typically as short as it is wide (0.5 cm) and drains directly into the vena cava. This configuration presents a surgical challenge that is discussed in more detail later in this chapter. In up to 20% of individuals, the right adrenal vein may drain into an accessory right hepatic vein and then into the vena cava, at or near the confluence of such a vein. Vigilance about this variant and others (Fig. 75.3) may reduce the likelihood of intraoperative venous hemorrhage during right adrenalectomy.

NORMAL HISTOPATHOLOGY

The adrenal cortex is approximately 2 mm thick and comprises more than 80% of the mass of the gland. It is made up of three

layers (Fig. 75.4). The outer *zona glomerulosa* is a thin layer of relatively small cells with moderately eosinophilic, lipid-poor cytoplasm. It has an undulating inner border and normally does not form a complete circumferential layer. Most of the adrenal cortex is formed by the *zona fasciculata,* a middle layer composed of long radial columns of large, clear, lipid-laden cells. The inner *zona reticularis* is made up of small nests of compact, eosinophilic cells. The adrenal medulla consists of clusters and short cords of chromaffin cells, which are large, polyhedral, and packed with basophilic secretory granules. Catecholamines within these granules yield a brown reaction when treated with chromium salts, giving the cells their name. In contrast to the cortex, the adrenal medulla is richly endowed with autonomic nerve fibers and ganglion cells. Sympathetic fibers synapse directly with the chromaffin cells, constituting an interface between the nervous and endocrine systems.

The microvasculature of the adrenal gland functionally unifies the cortex and medulla in a portal system configuration that is adapted to enhance the stress response. The adrenal arteries arborize extensively before entering the capsule to form a subcapsular plexus. Blood flows centripetally through capillaries in the zona glomerulosa and zona fasciculata before forming a deep plexus

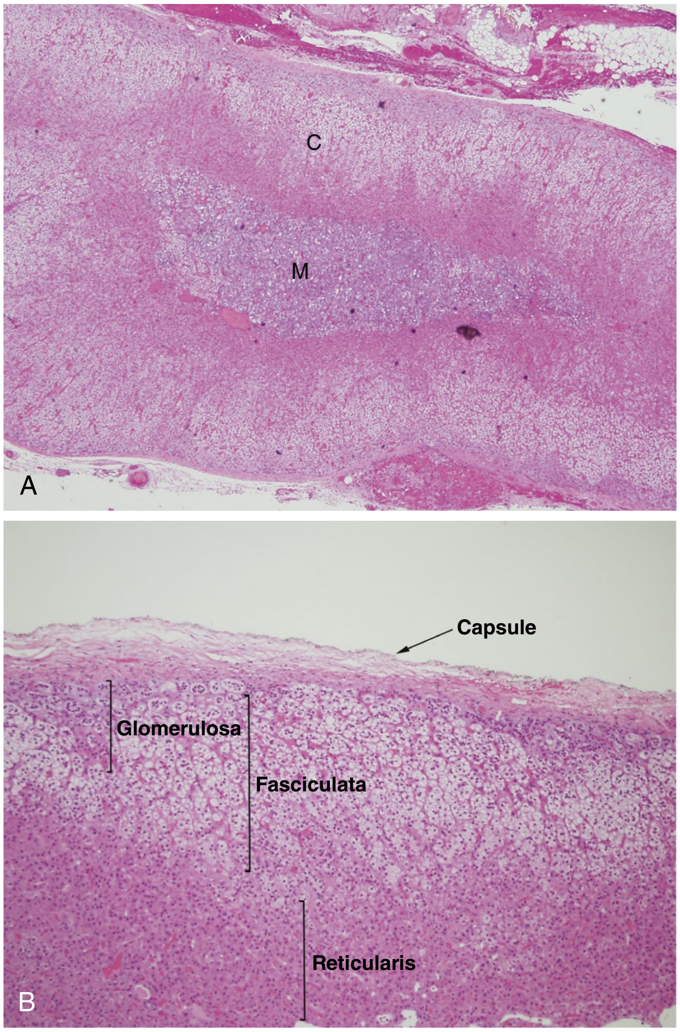

FIGURE 75.4 Normal adrenal histopathology. (A) Low-power view showing the adrenal cortex *(C)* and medulla *(M)*. (B) Medium-power view demonstrating individual layers of the adrenal cortex. The thickness of the zona glomerulosa varies along its length (hematoxylin and eosin stain). (Courtesy Dr. Anthony Gill.)

within the zona reticularis. From there, steroid-enriched postcapillary blood enters the medulla, where cortisol drives the expression of phenylethanolamine *N*-methyltransferase (PNMT). PNMT is responsible for the conversion of norepinephrine to epinephrine and is not expressed in extraadrenal paragangliomas.

BIOCHEMISTRY AND PHYSIOLOGY

Adrenal Steroid Biosynthesis

Adrenal steroid biosynthesis begins with the transport of cholesterol to the inner mitochondrial membrane by the steroidogenic acute regulatory protein (Fig. 75.5). Cholesterol then undergoes a series of oxidative reactions catalyzed predominantly by membrane-associated enzymes belonging to the cytochrome P450 (CYP) family. Cleavage of the cholesterol side chain yields the hormonally inactive compound pregnenolone, the immediate precursor to the adrenal steroid hormones. Serial oxidation by CYP17 converts pregnenolone and progesterone into the major adrenal sex steroids dehydroepiandrosterone (DHEA) and androstenedione. Additional enzymatic steps confined to the gonads generate testosterone, estrone, and estradiol from androstenedione. Oxidation of 17-hydroxypregnenolone by 3β-hydroxysteroid dehydrogenase followed by action of CYP21A2 and CYP11B1 yields cortisol, the active glucocorticoid hormone in humans. Aldosterone is generated by the oxidation of corticosterone by CYP11B2 within the zona glomerulosa. CYP17 expression is confined to the zona fasciculata and zona reticularis, accounting for the synthesis of glucocorticoids and adrenal sex steroids in these regions.

Steroid Hormone Physiology and Metabolism

Steroid hormones belong to a general class of low-molecular-weight, lipophilic signaling molecules that act by entering cells and binding to intracellular receptors. This group of hormones also includes thyroid hormone, retinoids, and vitamin D. Hormone binding results in alterations in gene expression that show a delayed and prolonged response compared with changes induced by peptide hormones, which act by binding to cell surface receptors. In the circulation, endogenous steroid hormones are largely bound to highly specific binding globulins. Serum levels of these proteins—and hence free hormone levels—can be altered by certain physiologic and disease states, such as pregnancy, nephrotic syndrome, and cirrhosis. Metabolism of both endogenous and pharmacologic steroids generally proceeds through hydroxylation, sulfonation, or conjugation to glucuronic acid in the liver, followed by urinary excretion. The regulation and physiologic actions of individual steroid hormones are discussed here.

Glucocorticoids

The release of corticotropin-releasing factor into the hypothalamic-pituitary portal system by hypothalamic neurons results in adrenocorticotropic hormone (ACTH) secretion by the anterior pituitary. ACTH binds to a G protein–coupled receptor on the adrenocortical cell surface and stimulates glucocorticoid secretion. Steroidogenesis is acutely upregulated by increased steroidogenic acute regulatory protein-mediated cholesterol transport and pregnenolone synthesis by CYP11A1. ACTH is released in a pulsatile fashion that normally displays a circadian rhythm. The highest level of ACTH, and therefore cortisol, is generally detected on waking, with levels gradually declining throughout the day to reach a nadir in the early evening. This pattern must be considered in evaluating patients for glucocorticoid deficiency or excess.

Glucocorticoid hormones have broad-ranging effects on almost all organ systems in the body. As a rule, they generate a catabolic state that characterizes the body's response to stress. The hormones are so named because they cause alterations in carbohydrate, protein, and lipid metabolism that have the net effect of increasing blood glucose concentrations. Hepatic glucose output is elevated by the upregulation of gluconeogenesis, and net glycogen deposition occurs. Glucose uptake by peripheral tissues is directly inhibited. Glucocorticoids stimulate lipolysis with release of free fatty acids into the circulation, and a general state of insulin resistance is induced, resulting in protein catabolism. Fatty acids and amino acids serve as energy sources and substrates for gluconeogenesis. In the cardiovascular system, glucocorticoids exert a permissive and enhancing effect on catecholamine signaling by sensitizing arterial smooth muscle cells to β-adrenergic stimulation and increasing catecholamine concentrations in neuromuscular junctions. Cardiac contractility and peripheral vascular tone are thus maintained, explaining why the hemodynamic collapse that accompanies acute adrenal insufficiency can be remedied by glucocorticoid administration.

Glucocorticoids are potent antiinflammatory and immunosuppressive agents. Acutely, glucocorticoids reduce circulating lymphocyte and eosinophil counts while increasing neutrophil counts. Lymphocyte apoptosis is promoted, cytokine and immunoglobulin production is decreased, and histamine release is suppressed. Glucocorticoids also reduce prostaglandin synthesis through inhibition of phospholipase A2.

Mineralocorticoids

Aldosterone release from the zona glomerulosa is principally regulated by angiotensin II and the blood potassium level. The renin-angiotensin-aldosterone axis is responsive to sodium delivery to the distal convoluted tubule of the kidney. Low sodium delivery, which occurs in states such as hypovolemia, shock, renal artery vasoconstriction, and hyponatremia, stimulates the release of renin from the juxtaglomerular apparatus. The prohormone angiotensinogen is synthesized by the liver and is cleaved to inactive angiotensin I by renin. Further cleavage of angiotensin I by angiotensin-converting enzyme (ACE) in the lungs and elsewhere yields angiotensin II, a potent vasoconstrictor and stimulator of aldosterone release. Hypokalemia reduces aldosterone release by suppressing renin secretion and also by acting directly at the zona glomerulosa. Hyperkalemia has the opposite effect.

Aldosterone regulates circulating fluid volume and electrolyte balance by promoting sodium and chloride retention by the distal tubule. Potassium and hydrogen ions are secreted into the urine. Acutely, expansion of the extracellular fluid volume and a rise in blood pressure are observed after aldosterone infusion. Negative feedback occurs primarily through an increase in sodium delivery to the distal tubule, suppressing renin release.

Adrenal Sex Steroids

Secretion of the adrenal androgens androstenedione, DHEA, and DHEA-S (the sulfonated derivative of DHEA, synthesized in the adrenal and liver) is regulated by ACTH and other incompletely understood mechanisms. Of the three, androstenedione is produced in the smallest quantities. The physiologic effects of adrenal sex steroids are generally weak in comparison with the gonadal sex steroids, particularly in males. In females, peripheral conversion of DHEA and DHEA-S to more potent androgens, including androstenedione, testosterone, and dihydrotestosterone, supports normal pubic and axillary hair growth and may play a role in maintaining libido and a sense of well-being.

Catecholamine Biosynthesis and Physiology

Synthesis of catecholamines in the adrenal medulla begins with the hydroxylation of tyrosine, a rate-limiting step that generates dihydroxyphenylalanine (L-dopa) in the cytosol (Fig. 75.6). Decarboxylation of L-dopa generates dopamine, which is then β-hydroxylated to form norepinephrine. Epinephrine is created by the action of phenylethanolamine *N*-methyltransferase, which, unlike the other enzymes involved in catecholamine synthesis, is localized to the chromaffin cells of the adrenal medulla and organ of Zuckerkandl. Sympathetic stimulation of the adrenal medulla results in the release of stored catecholamines into the circulation. Basal levels of adrenal catecholamine secretion are normally low, although large (up to fiftyfold) increases in levels may be observed in response to major physiologic or psychological stressors. Target tissue responses are mediated by α- and β-adrenergic receptors. α-Adrenergic receptors display greater affinity for norepinephrine compared with epinephrine, and the opposite is true for β-adrenergic receptors. Stimulation of β_1-adrenergic receptors in the myocardium results in increased heart rate and contractility. Stimulation of β_2-adrenergic receptors results in smooth muscle relaxation in tissues such as the uterus, bronchi, and skeletal muscle arterioles. α_1-Adrenergic receptors mediate vasoconstriction in tissues such as the skin and gastrointestinal tract. α_2-Adrenergic receptors exist in presynaptic locations in the central nervous system, where they mediate attenuation of sympathetic outflow. The net effect of adrenal catecholamine release is to augment blood flow and oxygen delivery to the brain, heart, and skeletal muscle, which are essential to the fight-or-flight response, but at the expense of other organ systems.

Catecholamine Clearance

Catecholamines are potent and short-acting compounds, with a plasma half-life on the order of 1 minute. Their presence in synapses and the circulation exhibits tight negative regulation by both reuptake and degradation. Degradation pathways merit some discussion because they generate the metabolites commonly measured in the biochemical evaluation of pheochromocytoma (see later). Epinephrine and norepinephrine are inactivated by one or both of the enzymes monoamine oxidase and catechol-*O*-methyltransferase (see Fig. 75.6). Initial methylation by catechol-*O*-methyltransferase yields metanephrine and normetanephrine, which can be detected in plasma and urine. Their relatively stable plasma levels, which contrast with the high-amplitude fluctuations seen in plasma epinephrine and norepinephrine levels, make them attractive diagnostic markers.[4] The sequential action of monoamine oxidase and catechol-*O*-methyltransferase generates the major final product, vanillylmandelic acid. Catecholamine metabolites are excreted in the urine, sometimes after sulfonation or conjugation to glucuronic acid in the liver.

ADRENAL INSUFFICIENCY

Types of Adrenal Insufficiency

Primary Adrenal Insufficiency (Addison Disease)

Originally described in patients with tuberculous destruction of the adrenal glands, Addison disease is a rare condition that manifests with weakness and fatigue, anorexia, nausea or vomiting, weight loss, hyperpigmentation, hypotension, and electrolyte disturbances (hyponatremia and hyperkalemia). Hyperpigmentation, previously believed to be caused by elevated levels of pro-opiomelanocortin and its cleavage product, α-melanocyte-stimulating hormone, is now believed to result from ACTH-induced melanogenesis.[5] Hormonal insufficiency caused by intrinsic adrenal disease arises from three general mechanisms: congenital adrenal dysgenesis/hypoplasia, defective steroidogenesis, and adrenal destruction. Of these, adrenal destruction from autoimmune causes is the most common, followed by infectious adrenalitis (e.g., tuberculous, fungal, viral), adrenal replacement by metastatic tumor, and adrenal hemorrhage (Waterhouse-Friderichsen syndrome). The last occurs in the setting of septicemia caused by meningococcal or other organisms and is more common in pediatric and asplenic patients.

Secondary Adrenal Insufficiency

Secondary adrenal insufficiency is a relatively common disorder resulting from ACTH deficiency, often occurring in the setting of pharmacologic steroid withdrawal. Patients receiving high supraphysiologic doses of glucocorticoids (more than the equivalent of 20 mg of prednisone daily; Table 75.1) for more than 5 days and

those receiving low supraphysiologic doses for more than 3 weeks are at risk for HPA axis suppression. Surgical cure of Cushing syndrome likewise results in glucocorticoid withdrawal. The rate of recovery from HPA axis suppression varies in accordance with the duration and severity of previous glucocorticoid excess, and the need for glucocorticoid supplementation may last several years.[6] Other less common causes of secondary adrenal insufficiency include panhypopituitarism caused by neoplastic or infiltrative replacement, granulomatous disease, and pituitary hemorrhage or infarction. Pituitary infarction may occur in the setting of severe postpartum hemorrhage (Sheehan syndrome).

Adrenal Insufficiency in the Critically Ill

Studies have suggested that critically ill patients with sepsis or systemic inflammatory response syndrome may be affected by acute reversible dysfunction of the HPA axis. The incidence of the disorder is approximately 30% in critically ill patients, although this figure may be higher in those with septic shock. Whether these patients incur increased mortality because of adrenal insufficiency remains to be defined. Proposed mechanisms of reversible HPA axis dysfunction include adrenal ACTH resistance and decreased responsiveness of target tissues to glucocorticoids. Glucocorticoid supplementation in septic patients has been the topic of at least 42 randomized controlled trials. Among these studies, corticosteroid administration was associated with a small reduction in 30-day mortality (1.8% absolute risk reduction) and faster shock reversal. There appears to be an inverse relationship between survival benefit and glucocorticoid dose, with physiologic (i.e., replacement) doses yielding a possible benefit and high supraphysiologic doses demonstrating significant harm. Adverse effects of corticosteroid administration in this patient population include hypernatremia, hyperglycemia, and muscle weakness. Earlier trials suggested that patients with severe septic shock, particularly those requiring vasopressors, may benefit from 5- to 7-day courses of glucocorticoids up to 300 mg/day or less of hydrocortisone or equivalent. As more recent data have not confirmed a significant survival benefit, glucocorticoid use should be individualized in critically ill patients.[7]

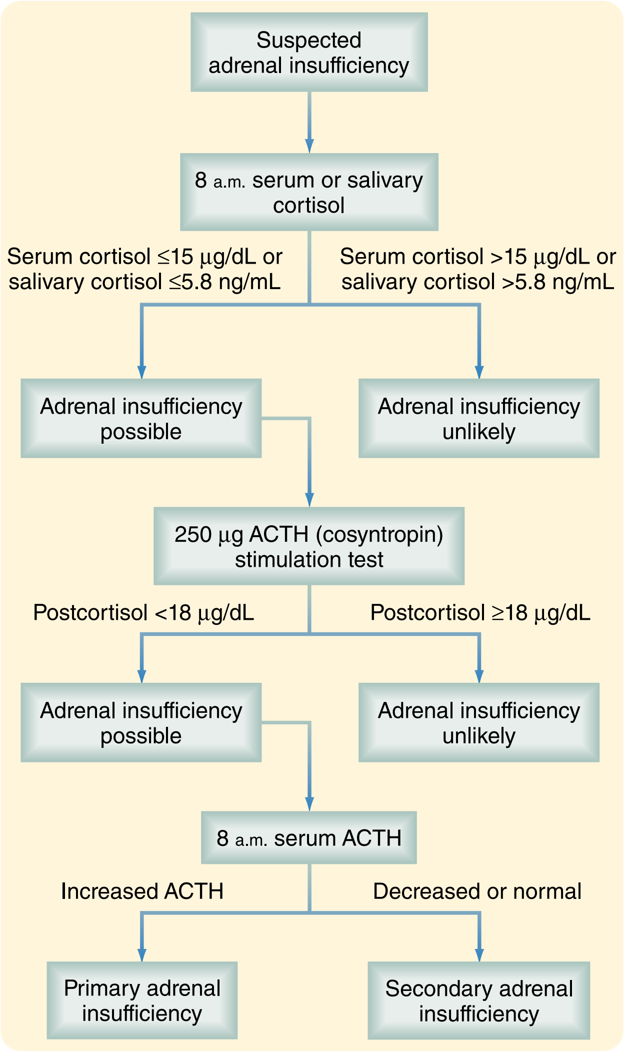
Adrenal Crisis

Acute adrenal insufficiency, or adrenal crisis, is a life-threatening condition that typically occurs in individuals with already marginal adrenocortical function who are subjected to a significant acute physiologic stressor, such as infection or trauma. Sudden and complete loss of adrenal function, as occurs with Waterhouse-Friderichsen syndrome and certain hypercoagulable states, can also be manifested with adrenal crisis. Clinical findings include shock, abdominal pain, fever, nausea and vomiting, electrolyte disturbances, and occasionally hypoglycemia. Mineralocorticoid deficiency, resulting in an inability to maintain sodium and intravascular volume, is the primary pathogenic mechanism, although diminished cardiovascular responsiveness to catecholamines caused by glucocorticoid deficiency also plays a role. Treatment for suspected adrenal crisis should not be delayed while awaiting the results of diagnostic testing. The treatment of adrenal crisis centers around large-volume intravenous resuscitation with isotonic saline and glucocorticoid administration in the form of hydrocortisone (100 mg intravenous bolus followed by 75 mg every 8 hours) or dexamethasone (4 mg intravenously every 24 hours). Dexamethasone is long acting and carries the advantage of not interfering with biochemical assays of endogenous glucocorticoid production. Mineralocorticoid replacement is not an early priority because the sodium- and fluid-retaining effects of mineralocorticoids are not manifested until several days after administration. Fluid and electrolyte balance can be rapidly achieved by saline infusion.

Diagnosis and Treatment

Diagnosis

As is true for most endocrine disorders, the diagnosis of adrenal insufficiency depends on maintaining sufficient clinical suspicion for the disease. The clinical manifestations have been discussed earlier. Surgeons are most likely to encounter patients with adrenal insufficiency in the intensive care unit, trauma suite, or operating room when treating patients with steroid-dependent chronic illnesses. Routine and provocative biochemical testing is necessary to confirm the diagnosis (Fig. 75.7). The first step is to document inadequate cortisol production, which can be done by measuring



Suspected adrenal insufficiency
8 a.m. serum or salivary cortisol
Serum cortisol ≤15 µg/dL or salivary cortisol ≤5.8 ng/mL
Serum cortisol >15 µg/dL or salivary cortisol >5.8 ng/mL
Adrenal insufficiency possible
Adrenal insufficiency unlikely
250 µg ACTH (cosyntropin) stimulation test
Postcortisol <18 µg/dL
Postcortisol ≥18 µg/dL
Adrenal insufficiency possible
Adrenal insufficiency unlikely
8 a.m. serum ACTH
Increased ACTH
Decreased or normal
Primary adrenal insufficiency
Secondary adrenal insufficiency

FIGURE 75.7 Algorithm for the diagnosis of adrenal insufficiency. The adequacy of cortisol production is initially assessed with morning cortisol level measurement. Patients with low or borderline values undergo provocative adrenocorticotropic hormone *(ACTH)* stimulation testing, with serum cortisol levels measured before and 30 to 60 minutes after the administration of ACTH. Failure to mount an adequate response to ACTH usually establishes the diagnosis of adrenal insufficiency. The cause of adrenal insufficiency is then investigated with a morning ACTH level measurement.

morning levels of cortisol in the serum or saliva. In most patients, morning serum cortisol concentration higher than 15 μg/dL or morning salivary cortisol concentration higher than 5.8 ng/mL effectively excludes adrenal insufficiency. Patients whose levels fall below these thresholds should undergo provocative testing. A high-dose cosyntropin stimulation test is performed by administering 250 μg cosyntropin and measuring serum cortisol levels 30 to 60 minutes later. A positive test result (i.e., a stimulated cortisol level less than 18 μg/dL) is strongly suggestive of adrenal insufficiency. After the diagnosis of adrenal insufficiency has been made, a morning ACTH level is determined to differentiate between primary and secondary adrenal insufficiency.

Treatment

The treatment of adrenal crisis has been discussed. The goal of maintenance therapy for chronic adrenal insufficiency is to replace physiologic glucocorticoid and mineralocorticoid levels. Daily adult cortisol production is approximately 30 mg per day, and this can be replaced by hydrocortisone administration (e.g., 20 mg in the morning and 10 mg in the evening). Typical mineralocorticoid replacement consists of fludrocortisone 0.1 mg/day. Commensurate increased dosages of glucocorticoids are needed during periods of minor and major physiologic stress, such as mild infections (minor) and trauma, significant infections, burns, or elective surgery (major).

Perioperative Steroid Administration. Recommendations concerning glucocorticoid administration during elective surgery have been based primarily on uncontrolled retrospective studies. The need for supraphysiologic doses of glucocorticoids in this setting has generally been overstated. Patients with primary adrenal insufficiency (Addison disease) are at increased risk for perioperative adrenal crisis because of their inability to increase endogenous cortisol production in response to stress. They generally require hydrocortisone 100 mg intravenously just before induction of anesthesia. Patients with secondary adrenal insufficiency caused by chronic glucocorticoid treatment for autoimmune or inflammatory conditions have only a 1% to 2% risk of hypotensive crisis without perioperative glucocorticoid coverage. To prevent this rare but hazardous complication, chronic glucocorticoid users should, at the least, be maintained on their usual glucocorticoid dosage throughout the perioperative period. Supplementation above this level should be given in short courses according to the guidelines listed in Table 75.2.[8] Patients undergoing unilateral adrenalectomy should be given supplemental glucocorticoids only if the underlying diagnosis is Cushing syndrome or mild autonomous cortisol secretion (MACS).

DISEASES OF THE ADRENAL CORTEX

Primary Aldosteronism

Epidemiology and Clinical Features

Primary aldosteronism, the unregulated release of excess aldosterone from one or both adrenal glands, was first described by Jerome Conn in 1954. Primary aldosteronism classically manifests with resistant hypertension and hypokalemia, although studies have revealed that most patients may be normokalemic, depending on the population screened. Hypokalemia is likely a manifestation of severe or late-stage disease. The prevalence of primary aldosteronism has been the topic of considerable debate. It was generally believed to affect approximately 1% of hypertensive patients. Widespread application of the aldosterone-to-renin ratio as a screening test in certain centers led to reports of a 10% to 40% prevalence of primary aldosteronism among hypertensive patients. There is some consensus that these higher figures reflect strong referral bias and that the actual prevalence in unselected hypertensive patients is likely to be 7% or less.[9] Nonselective use of the aldosterone-to-renin ratio to identify patients with primary aldosteronism is known to decrease the fraction of patients with surgically correctible disease (unilateral aldosteronoma) significantly, although the absolute number of surgically treatable cases has increased.

The mean age at diagnosis for primary aldosteronism is approximately 50 years, and the disease has a slight male predilection. Most patients are asymptomatic, although patients with significant hypokalemia may report muscle cramps, weakness, or paresthesias. Patients typically have moderate to severe hypertension that is refractory to medical therapy. It is common for patients with primary aldosteronism to require two to four antihypertensive medications. Responsiveness to mineralocorticoid antagonists such as spironolactone or eplerenone may be seen—a feature that is predictive of a good response to surgical treatment.

Primary aldosteronism is a potentially curable cause of significant cardiovascular disease. A study comparing 270 subjects with biochemically confirmed primary aldosteronism with case-matched hypertensive controls has revealed that primary aldosteronism is associated with a significantly increased risk of stroke, myocardial infarction, arrhythmias including atrial and ventricular fibrillation, and heart failure.[10] These results add to existing evidence indicating that the adverse cardiovascular sequelae of primary aldosteronism are more pronounced than those caused by blood pressure elevation alone. Surgical correction of primary aldosteronism leads to regression of many of these adverse physiologic changes.

TABLE 75.2 Perioperative Glucocorticoid Regimens for Patients With Secondary Adrenal Insufficiency[a]

DEGREE OF SURGICAL STRESS	EXAMPLES	INTRAOPERATIVE GLUCOCORTICOID DOSAGE	GLUCOCORTICOID TAPER
Minor	Procedures under local anesthetic, most outpatient procedures, inguinal hernia repair	None (take usual morning steroid dosage)	None (continue to take usual dosage)
Moderate	Routine abdominal, peripheral vascular, or orthopedic surgery	Hydrocortisone 50 mg or equivalent before procedure	Hydrocortisone 25 mg every 8 hours for 24 hours, then resume usual dosage
Major	Resection of gastrointestinal cancer, cardiopulmonary bypass	Hydrocortisone 100 mg or equivalent before procedure	Hydrocortisone 50 mg every 8 hours for 24 hours, then taper by half every day to usual dosage

[a] Caused by chronic pharmacologic steroid use.

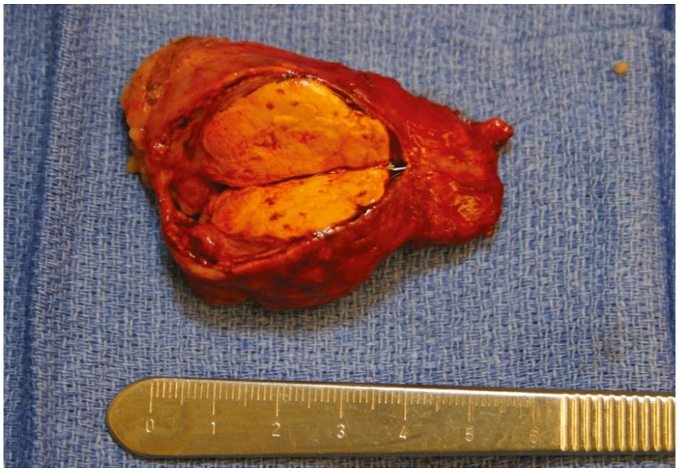


FIGURE 75.8 Classic canary-yellow aldosteronoma.

TABLE 75.3 Causes of Primary Aldosteronism

	SCREENING[a]	
CAUSE	SELECTIVE (%)	NONSELECTIVE (%)
Aldosterone-producing adenoma	60	30
Bilateral adrenal hyperplasia (idiopathic hyperaldosteronism)	35	65
Aldosterone-producing adrenocortical carcinoma	<1	<1
Familial hyperaldosteronism		
Type I (glucocorticoid-remediable aldosteronism)	<1	<1
Type II (non–glucocorticoid-remediable aldosteronism)	<1	<1

[a] Rates of specific pathologic processes are highly dependent on the pattern of screening (selective vs. nonselective).

The most common causes of primary aldosteronism are unilateral aldosterone-producing adenomas (aldosteronomas; Fig. 75.8) and bilateral adrenal hyperplasia (also termed *idiopathic hyperaldosteronism;* Table 75.3). In the past, aldosteronoma was present in more than 60% of cases, but this number has decreased substantially as nonselective screening with the aldosterone-to-renin ratio has been applied. This phenomenon may reflect increased detection of hyperplasia, which is characterized by milder biochemical abnormalities than aldosteronoma. Recent sequencing has revealed somatic mutations in genes coding for ion channels and ATPase in 94% of aldosterone-producing adenomas.[11]

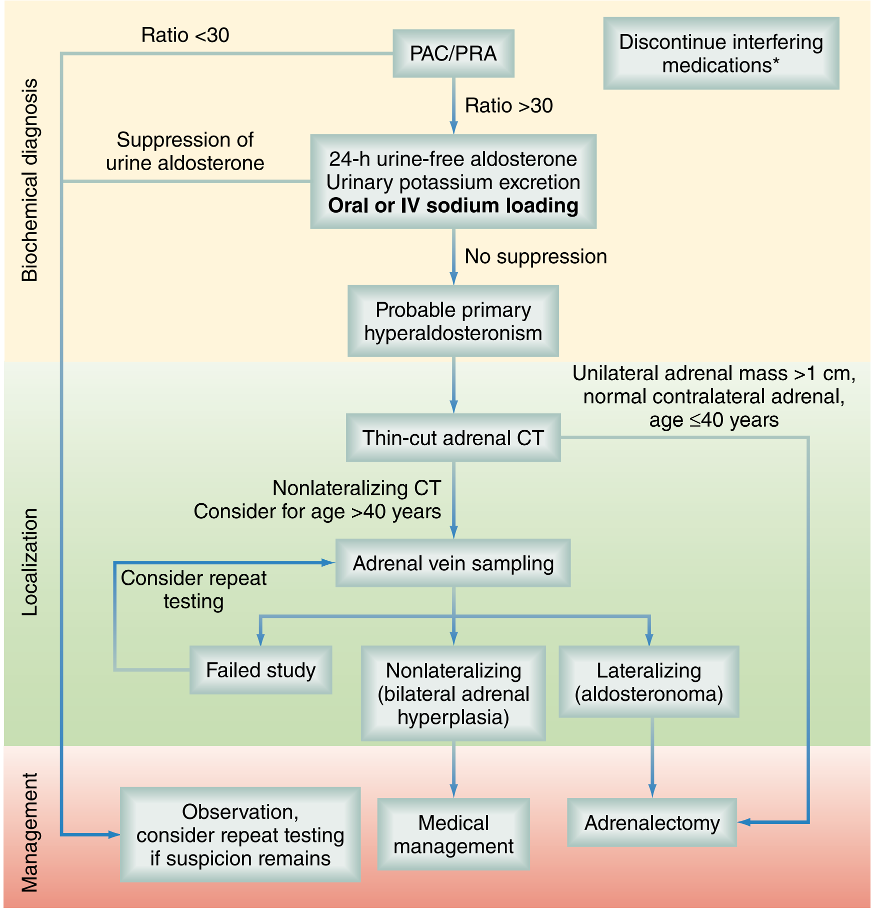
Diagnosis and Localization

Biochemical diagnosis. The goal of diagnostic testing is to identify patients with primary aldosteronism and to perform subtype differentiation to optimize management. Biochemical screening should be performed in all patients with hypertension and unexplained hypokalemia, hypertension and an adrenal nodule, hypertension and sleep apnea, early-onset hypertension, and treatment-resistant hypertension. Establishing the diagnosis of primary aldosteronism begins with determining the ratio of plasma aldosterone concentration to plasma renin activity (expressed here as ng/dL divided by ng/[mL • hr]; Fig. 75.9). This test is optimally performed after discontinuation of interfering medications. Variable cutoff values for the aldosterone-to-renin ratio have been used in the literature, with the most commonly cited value of 30 yielding a sensitivity of approximately 90%. Some centers have advocated a lower threshold of 20; this increases sensitivity at some cost to specificity and conceptually reflects appreciation of the clinical gravity of failing to diagnose surgically correctable hyperaldosteronism.[12] A subset of patients with essential hypertension will have suppressed renin levels, which may result in false elevations of the aldosterone-to-renin ratio. Thus, the inclusion of an absolute aldosterone concentration higher than 15 mg/dL increases the specificity of initial screening. Patients who test positive and are younger than 30 years should be genetically screened for glucocorticoid-remediable aldosteronism (familial hyperaldosteronism type I), especially if they have a family history of early-onset hypertension. This rare autosomal dominant condition results in abnormal regulation of aldosterone synthesis by ACTH and can be medically treated.

Confirmatory biochemical testing is aimed at demonstrating inappropriately high (nonsuppressible) aldosterone levels by creating a state of hypervolemia-sodium excess. This may be done with either intravenous saline loading (2–3 L of isotonic saline given during 4–6 hours, followed by measurement of plasma aldosterone) or oral salt loading (200 mEq = 5000 mg sodium daily for 3 days, followed by measurement of 24-hour urine aldosterone excretion). Some centers administer high-dose fludrocortisone (0.1 mg every 6 hours) during oral salt loading to increase the specificity of suppression testing, but this method has not been widely adopted.

Subtype differentiation. After the diagnosis has been confirmed, subtype differentiation to determine unilateral versus bilateral causes of hyperaldosteronism is performed. Studies may include adrenal venous sampling (AVS), anatomic imaging, and sometimes functional scanning. The fact that most aldosteronomas are smaller than 15 mm in maximum dimension poses some challenges to localization. Thin-cut (3 mm) adrenal computed tomography (CT) scanning may have utility in identifying small adrenal nodules (Fig. 75.10). Additionally, primary aldosteronism can be caused by microscopic islands of CPY11B2 overexpressing cells that are only detectable postoperatively on immunohistochemical staining. This fact highlights the importance of adrenal vein sampling before offering surgical management of primary aldosteronism.

The gold standard for subtype differentiation is AVS. This test relies on the simultaneous measurement of cortisol and aldosterone levels in the peripheral circulation (inferior vena cava) and left and right adrenal veins (Fig. 75.11). More than a threefold elevation of the cortisol concentration in a sample relative to peripheral blood indicates successful cannulation of an adrenal vein and is referred to as the *selectivity index*. Lateralization is indicated by an unbalanced ratio of aldosterone to cortisol in the left and right adrenal veins, with the ratio on one side being fourfold higher than the other to identify the culprit gland. Considerable controversy exists about which patients should undergo AVS, an invasive procedure with a 90% technical success rate in experienced hands. There is clear consensus that AVS should be applied in all cases in which the biochemical diagnosis of primary aldosteronism has been confirmed and thin-cut adrenal CT reveals no abnormalities or bilateral abnormalities. Of the remaining patients who have a unilateral mass on CT scan, a small but not insignificant fraction (2%–10%) will represent false-positive localization and have persistent hyperaldosteronism after unilateral



Biochemical diagnosis
Localization
Management
Ratio <30
PAC/PRA

Medical management
Adrenalectomy

*Including spironolactone, ACE inhibitors, diuretics, β-blockers.

FIGURE 75.9 Algorithm for diagnosis, localization, and management of primary aldosteronism. Initial screening is done with determination of the PRA/PAC ratio, followed by confirmatory testing with sodium loading. After the biochemical diagnosis has been established, noninvasive localization is attempted with computed tomography *(CT)*. Patients with clear CT evidence of a unilateral abnormality can proceed to adrenalectomy with a more than 90% cure rate. Adrenal vein sampling is done in patients with equivocal CT findings and older patients, especially those older than 60 years, because nonfunctional cortical adenomas are found in 4% or more of this population and can cause false-positive CT localization. *ACE,* Angiotensin-converting enzyme; *PAC,* plasma aldosterone concentration, in ng/dL; *PRA,* plasma renin activity, in ng/(mL • hr).

adrenalectomy. In these patients, the adrenal mass represents a nonfunctioning cortical adenoma, and the true underlying diagnosis is a contralateral microaldosteronoma or bilateral adrenal hyperplasia, the latter of which is not surgically remediable.

Because patients 40 years and older are more likely to possess nonfunctioning adrenal cortical adenomas, some authors have advocated AVS in all patients 40 years of age and older, and others have recommended universal application of this test in the evaluation of primary aldosteronism.[12] Young patients with a unilateral cortical adrenal mass larger than 1 cm in diameter and a normal contralateral adrenal gland on CT can proceed directly to adrenalectomy, as their management is rarely changed by AVS results, whereas those without definitive CT localization undergo AVS.[13] In consideration of the body of literature, we advocate for more liberal application of AVS for patients 40 years and older.

Practically speaking, approximately 30% to 40% of patients being evaluated for primary aldosteronism undergo AVS when it is applied to select patients. The usefulness of the test is limited by its low success rate in some reports (40%–80%), with the most common reason for incomplete AVS being failure to cannulate the right adrenal vein. Frequently, however, sufficient lateralizing information is provided during AVS to guide surgical treatment, even when the study is not bilaterally selective.[14] AVS is also limited by access, as it may only be available at specialized centers.

Surgical Management and Outcomes

Minimally invasive adrenalectomy is the preferred procedure for the management of aldosteronoma and most other adrenal tumors.[15] Cure of primary aldosteronism is defined by clinical and biochemical end points. Reductions in blood pressure, antihypertensive medication requirements, and plasma and urine aldosterone levels and resolution of hypokalemia (if previously present) are observed as soon as 24 hours after successful surgery. Overall cure rates range from 75% to 95% at specialty centers, depending on the specific criteria for cure that are used. The Primary Aldosteronism Surgical Outcome (PASO) study established an international consensus for outcomes after adrenalectomy.[15] Clinical success is defined as complete (normalization of blood pressure without antihypertensive medication), partial (decrease in antihypertensive medication or reduction in blood pressure with same medication), or absent. Biochemical success is defined as complete (correction of hypokalemia and normalization of aldosterone-to-renin ratio), partial (correction of hypokalemia and ≥50% decrease in plasma aldosterone but persistently elevated aldosterone to renin ratio), or absent. In general, more than 80% of patients can expect either normalization of blood pressure or a significant reduction in antihypertensive medication requirements (typically, from three to four medications down to one). In some patients, depending on the degree of preoperative sodium overload, blood pressure may take several weeks to improve. Our practice is to stop all mineralocorticoid antagonists, ACE inhibitors, and angiotensin receptor blockers (ARBs) immediately after surgery, with tapering of β-blockers and α-blockers, which must be done to avoid a rebound phenomenon. Calcium channel blockers may be maintained at the clinician's discretion. For those patients who continue to be hypertensive in the short term, medications may be added back temporarily, as needed, until the blood pressure gradually reaches a new equilibrium over time.

Patients with hyperaldosteronism have a higher incidence of chronic kidney disease compared with hypertensive controls. Glomerular hyperfiltration caused by hyperaldosteronism can artificially raise creatinine clearance and mask renal insufficiency. After adrenalectomy, the decrease in aldosterone levels can lower glomerular filtration and unmask the true degree of chronic kidney disease. In addition, hyperkalemia caused by transient suppression of the contralateral adrenal gland may occur in 5% to 10% of patients after adrenalectomy for hyperaldosteronism.[16] Renal insufficiency and suppression of aldosterone secretion from the contralateral adrenal gland at AVS are predictors of hyperkalemia. Hyperkalemia occurs within 1 to 3 weeks after surgery; therefore, patients should be monitored with weekly serum potassium levels for 1 month postresection. Persistent hyperkalemia can be treated with mineralocorticoid replacement therapy (fludrocortisone).

A subset of patients with the following preoperative clinical characteristics experience reduced benefit from surgical treatment and continue to require antihypertensive medications after operation: males older than 45 years, family history of hypertension, long-standing hypertension, requirement of more than two antihypertensive medications, and nonresponse to spironolactone. These factors may indicate a component of essential hypertension or irreversible cardiovascular alterations caused by chronic disease, or both. On the basis of these clinical features, patients should be appropriately counseled as to what they should expect to gain from surgery.

Cushing Syndrome

Epidemiology and Clinical Features

The clinical features of glucocorticoid excess were first documented by Harvey Cushing in 1912 in his book, *The Pituitary Body*. He described a young female of "extraordinary appearance" who developed obesity, hirsutism, amenorrhea, easy bruising, and extreme muscle weakness. When evaluating a patient for Cushing syndrome, clinical signs and symptoms that can be present include visceral and truncal obesity, muscle weakness and atrophy, insulin resistance/type 2 diabetes, hypertension, abdominal striae, moon face, dorsocervical fat pad, hirsutism, easy bruising, and thinning of the skin. When left untreated, Cushing syndrome can be a lethal disease. The physiologic derangements resulting from glucocorticoid excess, including hypertension (present in >70% of cases), hyperglycemia, and truncal obesity, ultimately yield a fivefold excess mortality, primarily because of cardiovascular complications.[17,18] Thus, all efforts should be made to identify the root cause of cortisol excess and appropriately treat patients with Cushing syndrome. The differential diagnosis for the underlying cause of Cushing syndrome is broad, and the initial workup must consider ACTH-dependent and ACTH-independent causes (Fig. 75.12).

The most common cause of Cushing syndrome is pharmacologic glucocorticoid use for the treatment of inflammatory disorders. Endogenous Cushing syndrome is rare, affecting 5 to 10 individuals/million. Of these, most affected individuals (75%) will have Cushing *disease,* that is, glucocorticoid excess caused by an ACTH-hypersecreting pituitary adenoma. The remainder will be split between primary adrenal Cushing syndrome (15%) and ectopic ACTH syndrome (<10%), the latter of which usually is caused by neuroendocrine tumors or bronchogenic malignant neoplasms arising in the thorax.

Biochemical Diagnosis and Localization

The diagnosis of Cushing syndrome is reliant on demonstration of inappropriate cortisol secretion or the loss of physiologic negative feedback. Normally, cortisol release follows a predictable circadian rhythm, peaking approximately 1 hour after waking and reaching a nadir around midnight. Thus, inappropriate cortisol secretion can be detected as elevated cortisol release during a 24-hour period or as a higher-than-expected level in the late evening. The 1-mg overnight dexamethasone suppression test is commonly used to diagnose autonomous cortisol secretion. Late night salivary cortisol testing has provided a feasible alternative to suppression testing.

More than 90% of circulating cortisol is bound to plasma proteins. Unbound cortisol can be detected in the urine and saliva, and assessment of these body fluids forms the basis of biochemical screening for Cushing syndrome (Fig. 75.13); 24-hour urine collection for urine-free cortisol should be performed at least twice for initial screening. Unequivocally elevated levels should prompt immediate further testing to determine the cause and subtype of Cushing syndrome (i.e., primary adrenal cause, pituitary cause, and ectopic ACTH syndrome). Patients with moderately elevated 24-hour urine cortisol levels should undergo confirmatory testing with two late night salivary cortisol measurements. A high cutoff value of 550 ng/mL has a sensitivity of 93% and specificity of 100%.[19]

ACTH-independent. Primary adrenal Cushing syndrome, also termed *ACTH-independent Cushing syndrome,* is caused by autonomous adrenal cortisol production and therefore is generally associated with an undetectable ACTH level (<5 pg/mL) because of feedback inhibition. The underlying pathologic process is variable, with solitary adrenal adenoma found in approximately 90% of cases, adrenocortical carcinoma (ACC) in less than 10%, and bilateral micronodular or macronodular hyperplasia in less than 1%. Almost all these lesions, except micronodular hyperplasia, are readily apparent on CT scans.

ACTH-dependent. Hypercortisolemia associated with normal or elevated ACTH levels is indicative of ACTH-dependent Cushing syndrome, most commonly caused by a pituitary corticotroph

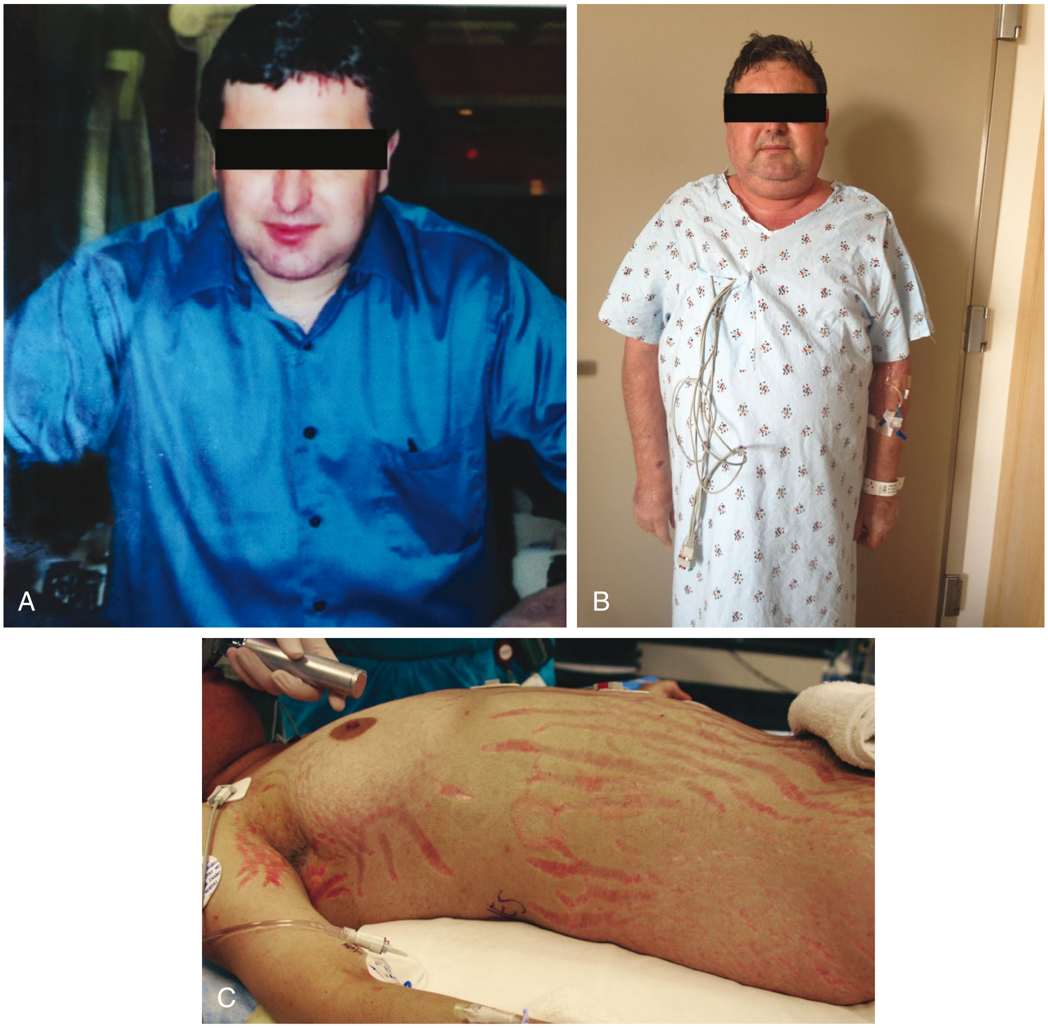

FIGURE 75.12 Clinical manifestations of Cushing syndrome. (A) Appearance of a male patient before development of Cushing syndrome. (B) Same patient 1 year after development of Cushing syndrome. (C) Purple abdominal and axillary striae in a male patient with Cushing syndrome.

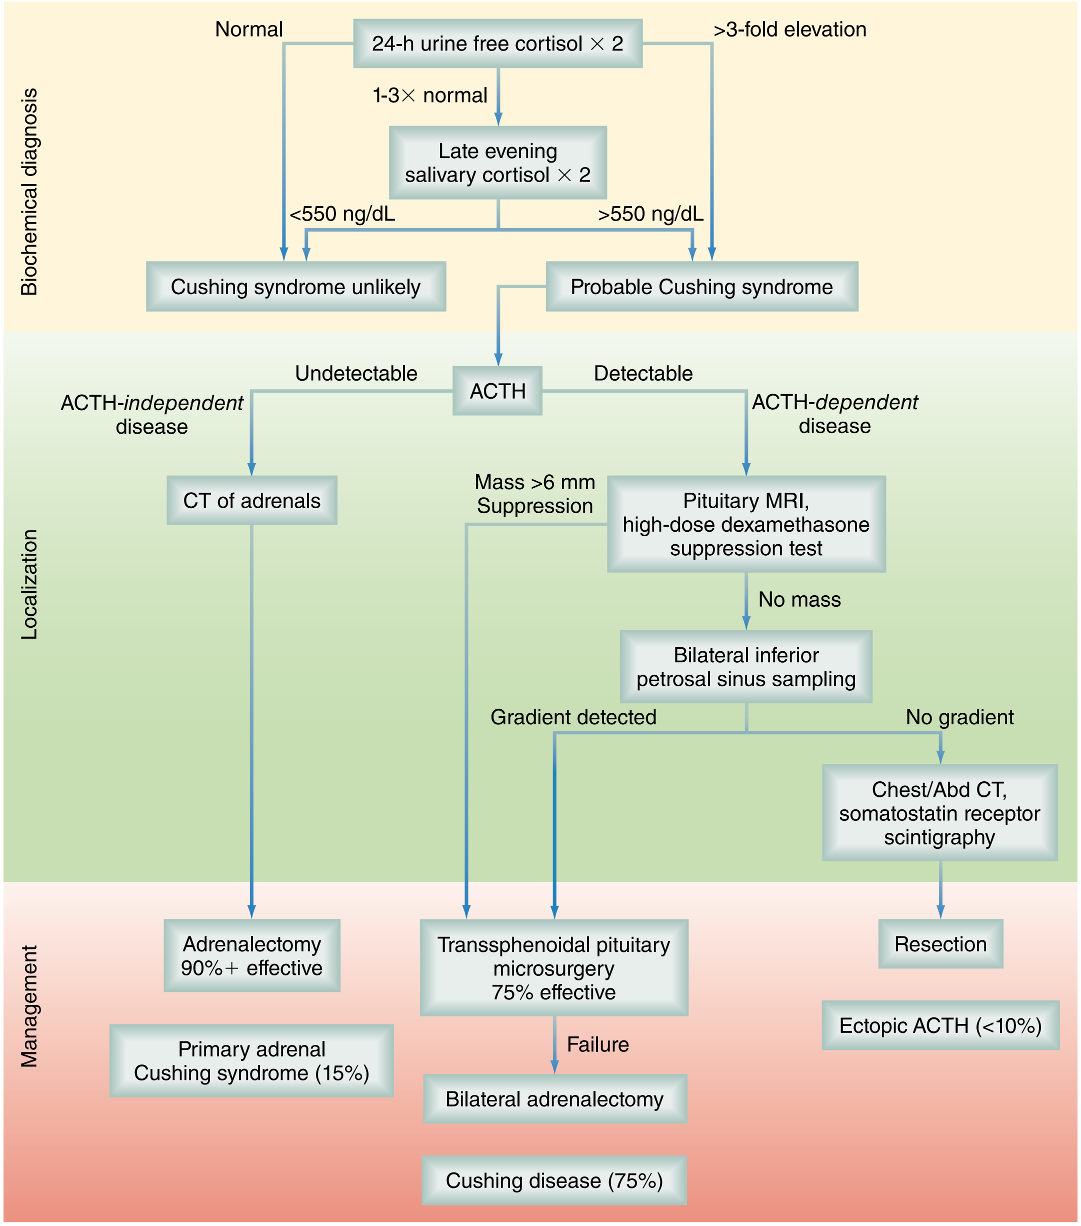
microadenoma (Cushing disease). Suspicion for ACTH-dependent Cushing syndrome should prompt pituitary imaging and high-dose dexamethasone suppression testing, that is, serum or urine cortisol measurement after administration of 2 mg of dexamethasone every 6 hours during 48 hours. Dexamethasone is chosen because it does not cross-react with biochemical assays for cortisol. Corticotroph adenomas are commonly suppressed in response to high-dose dexamethasone administration, whereas ectopic ACTH sources are completely lacking in feedback inhibition. Slightly more than 50% of corticotroph microadenomas are visible on pituitary magnetic resonance imaging (MRI). Detection of a pituitary mass larger than 6 mm in diameter in a patient with ACTH-dependent Cushing syndrome that is suppressed with high-dose dexamethasone justifies proceeding to pituitary surgery.[20] In the absence of a demonstrable mass, bilateral inferior petrosal sinus ACTH sampling with corticotropin-releasing factor stimulation should be pursued. Demonstration of a central-to-peripheral ACTH gradient in a study performed by a skilled physician is sufficient to diagnose Cushing disease. The absence of a clear gradient should prompt CT imaging of the chest and abdomen and, occasionally, somatostatin receptor scintigraphy to identify an ectopic ACTH source.

Surgical Management and Outcomes

Perioperative and postoperative glucocorticoid administration is obviously essential in the care of patients with Cushing syndrome. For patients undergoing adrenalectomy for Cushing syndrome, perioperative stress-dose steroids (e.g., hydrocortisone 100 mg intravenously every 8 hours for 24 hours) are recommended. In the most common scenario of resection of a solitary adrenal Cushing adenoma, steroids can usually be tapered to physiologic replacement levels during the course of several weeks. However, a subset of patients with Cushing syndrome of longer duration and severity will demonstrate lasting HPA axis suppression, requiring glucocorticoid supplementation for longer periods, sometimes longer than 1 year.

The management of patients who undergo pituitary surgery for Cushing disease is variable. In some centers, glucocorticoids are withheld during the immediate postoperative period to provide a window during which early remission may be assessed.[21] A subnormal morning cortisol level on postoperative day 1 or 2 is indicative of cure. Glucocorticoid supplementation is then resumed until the HPA axis recovers, usually for at least 6 months. Because of the significant risk of postoperative adrenal crisis in patients with Cushing syndrome of all subtypes, glucocorticoid



Biochemical diagnosis

FIGURE 75.13 Algorithm for the diagnosis, localization, and management of endogenous Cushing syndrome. A biochemical diagnosis can be established with an unequivocally elevated 24-hour urine-free cortisol level (greater than a threefold elevation) or an elevated late evening salivary cortisol level. Most cases of Cushing syndrome are caused by Cushing disease (pituitary corticotroph microadenoma) in which the plasma adrenocorticotropic hormone *(ACTH)* level is elevated. An undetectable ACTH level establishes the diagnosis of ACTH-independent Cushing syndrome and prompts adrenal imaging. Bilateral adrenalectomy is considered for patients with Cushing disease not cured by transsphenoidal surgery. *Abd,* Abdomen; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

management is ideally done in conjunction with an experienced endocrinologist.

Adrenalectomy is more than 90% effective in the treatment of primary adrenal Cushing syndrome. Resolution of symptoms typically takes months to years, and certain deleterious physiologic effects regarding bone density, body composition, and inflammation are extremely persistent.[22] Failures may result from local and occasionally distant tumor recurrence in the case of malignant disease. For Cushing disease, pituitary microsurgery, typically performed via a transnasal transsphenoidal approach, is approximately 90% successful in expert hands. Remission rates may be improved by reoperation or pituitary irradiation for patients whose basal cortisol levels do not fall appropriately after initial surgery. Laparoscopic or retroperitoneoscopic bilateral adrenalectomy may be considered for patients with Cushing disease in whom pituitary surgery and medical management have failed. Patients with Cushing syndrome are hypercoagulable and carry a risk of venous thromboembolism of up to 5% after pituitary or adrenal surgery. Chemical thromboprophylaxis should be considered, although there are insufficient data to determine the optimal duration and dosage.[23,24]

Special Case: Mild Autonomous Cortisol Secretion

MACS has replaced the term *subclinical Cushing syndrome*. Patients with MACS typically have incidentally discovered adrenal masses and biochemical evidence of cortisol hypersecretion without overt signs or symptoms of Cushing syndrome. This disease entity has been incompletely characterized with respect to its physiologic consequences and natural history. A serum cortisol level of >50 nmol/L (>1.8 μg/dL) after a 1-mg dexamethasone suppression test is considered consistent with MACS in the absence of overt signs or symptoms of hypercortisolism.

Hypertension, dyslipidemia, and impaired glucose tolerance appear to be more prevalent among individuals with MACS compared with normal individuals. Retrospective studies suggest that this subset of patients experiences improvement in obesity, hypertension, glycemic control, and dyslipidemia when they are treated surgically.[25] Furthermore, a randomized controlled trial comparing surgery with observation in 45 patients with MACS noted more frequent resolution of hypertension and other metabolic conditions in the surgically treated group.[26] We observe a continuum of disease ranging from subclinical to overt Cushing syndrome, which arises as a function of both symptom severity and the perceptiveness of the treating physician. Patients along the entire spectrum appear to benefit from restoration of normal cortisol physiology. We therefore recommend surgery for patients with MACS and comorbid conditions associated with hypercortisolism who are appropriate surgical candidates, especially for patients with larger (3- to 4-cm) tumors and those whose tumors enlarge on serial imaging studies.

Sex Steroid Excess

Adrenal tumors causing clinical features of sex steroid excess are rare. Most of these tumors are virilizing (as opposed to feminizing) and may be manifested at a late stage in association with an ACC. Almost all feminizing tumors are malignant, whereas approximately one-third of virilizing tumors are malignant. Of ACCs, 20% cause virilization, with most of these cases occurring in children. An additional 24% of ACCs will display mixed features of Cushing syndrome and virilization.[27] Virilizing tumors may be biochemically detected by measurements of 24-hour urine testosterone, DHEA, and DHEA-S. Although minimally invasive adrenalectomy remains the preferred procedure for most adrenal tumors, the high probability of malignancy in sex steroid–producing tumors merits close radiographic and intraoperative inspection for evidence of invasion or metastasis. Open adrenalectomy should be considered for obviously malignant tumors.

Adrenocortical Carcinoma

ACC is a rare tumor with an annual incidence of approximately 1/million. It demonstrates no significant sex predilection. At the time of presentation, ACCs tend to be very large (mean tumor size, 9–13 cm) and have usually spread beyond the confines of the adrenal gland.[28] Historically, 5-year overall survival rates have been in the 15% to 20% range. Among patients who undergo surgical resection, 5-year survival is approximately 40%, a figure that has essentially remained unchanged during the past two decades.[29] A higher risk of death is associated with increasing age of the patient, poorly differentiated or high-grade tumors, positive surgical margins, and presence of distant metastases. More than 50% of ACCs are functional. Cushing syndrome is most commonly seen, followed by virilization. Radiographic evaluation is primarily performed with CT, which typically reveals a heterogeneous mass with irregular or indistinct borders, central necrosis, and invasion of adjacent structures (Fig. 75.14). Metastases to lymph nodes, liver, and lungs may be found; therefore, preoperative staging evaluation with a minimum of CT scan of the chest is indicated. Fluorodeoxyglucose (FDG) position emission tomography (PET)/CT may be of benefit in patients with a high suspicion for metastatic disease.

Surgery is the only potentially curative treatment for ACC. Therefore, aggressive surgery is typically indicated for isolated tumors or locoregional disease. Classic teachings recommend open surgery; however, for small stage 1 and stage 2 tumors, survival appears similar for open and minimally invasive techniques when performed by experienced surgeons.

Treatment of large ACCs requires radical resection, which is most commonly achieved by an open approach. Complete resection can be achieved in up to 70% of patients in experienced hands. This frequently involves en bloc resection of adjacent organs or regional lymphadenectomy. Particular care must be taken in dealing with right-sided ACCs because direct tumor thrombus extension into the inferior vena cava and sometimes the right side of the heart may be observed. Tumors demonstrating intravascular extension may need to be resected while the patient is on cardiopulmonary bypass to reduce the likelihood of lethal intraoperative tumor embolization.[30]

Patients who undergo incomplete resection of ACCs have extremely limited life expectancy (median survival <1 year). Even those who undergo successful surgery are prone to development of local recurrence and metastases, which typically occur within 2 years. The principal chemotherapeutic agent for the treatment of ACC is mitotane [*o,p*-DDD, or 1,1-dichloro-2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl)ethane], a derivative of the insecticide DDT that is a direct adrenocortical toxin. Mitotane has been used clinically as an adjuvant to surgery and as primary therapy in individuals with unresectable or metastatic disease. A multinational retrospective study examining the efficacy of adjuvant mitotane after radical surgery has demonstrated a significant improvement in recurrence-free survival.[31] The use of mitotane is

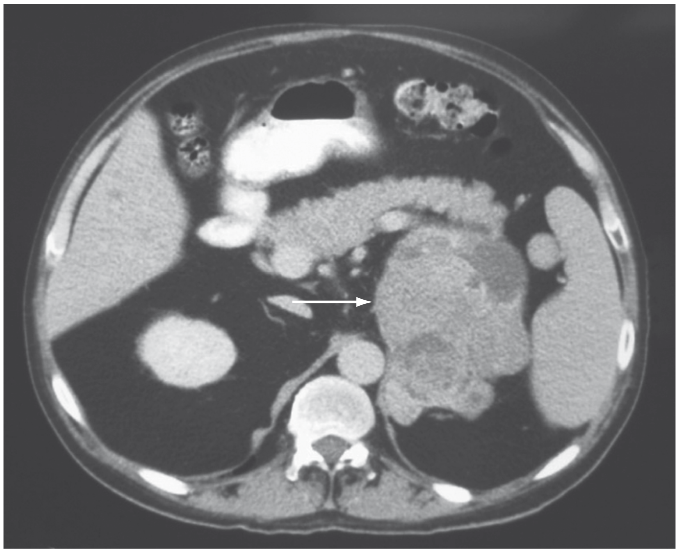

FIGURE 75.14 Computed tomography scan demonstrating a 10-cm left adrenocortical carcinoma. Note the area of central necrosis *(arrow)*.

limited by significant, dose-dependent gastrointestinal and neurologic toxicity. The multinational First International Randomized Trial in Locally Advanced and Metastatic Adrenocortical Carcinoma Treatment (FIRM-ACT) trial randomized 304 patients with locally advanced or metastatic ACC to receive etoposide, doxorubicin, cisplatin, and mitotane or streptozotocin and mitotane. There was a significantly improved response rate and progression-free survival in the former group, but median overall survival remained poor in both groups (14.8 vs. 12.0 months).[32] Several other trials are examining targeted agents such as epidermal growth factor inhibitors, insulin-like growth factor I inhibitors, antiangiogenic agents, and broad-spectrum tyrosine kinase inhibitors. There is also an emerging interest in individualized therapy based on genomic and expression profiling of tumors.

DISEASES OF THE ADRENAL MEDULLA

Pheochromocytoma

Epidemiology and Clinical Features

The first account of pheochromocytoma was published in 1886 by Felix Frankel, who described a young female suffering from intermittent attacks of palpitations, anxiety, vertigo, and headache. Autopsy revealed bilateral adrenal tumors that stained brown when treated with chromium salts. Because of the characteristic positive chromaffin reaction, these adrenomedullary tumors are termed *pheochromocytoma* (dusky-colored tumor, from the Greek *phaios*, dusky). Successful surgical management of pheochromocytoma was initially described in 1926 by César Roux followed by Charles Mayo in 1927.[33]

Pheochromocytoma affects approximately 0.2% of hypertensive individuals. Males and females are affected equally. The peak incidence in sporadic cases is between the ages of 40 and 50 years, whereas familial cases tend to manifest at earlier ages. A subset of patients present with the classic triad of headache, diaphoresis, and palpitations, although almost all patients will display at least one of these symptoms. Hypertension is present in 90% of cases and may be episodic or sustained. The principal challenge in making the diagnosis of pheochromocytoma arises from the fact that essential hypertension is common and the clinical features suggestive of pheochromocytoma are nonspecific. In fact, only 0.5% of patients with hypertension and suggestive features will ultimately prove to have the disease. The differential diagnosis of pheochromocytoma is broad, encompassing diverse processes such as hyperthyroidism, hypoglycemia, coronary artery disease, heart failure, stroke, drug-related effects, and panic disorder. Pheochromocytoma has been described as a biologic time bomb because of the potentially lethal cardiovascular effects of the bioactive compounds secreted by these tumors. Thus, despite the challenges in diagnosis, clinicians should screen for this disease aggressively and seek appropriate treatment for affected patients. Conversely, a growing number of pheochromocytomas identified incidentally on imaging may be minimally secreting; these so-called “silent pheos” may require a high clinical index of suspicion for diagnosis.

Previously, pheochromocytoma was termed the *10% tumor,* suggesting that 10% are bilateral, 10% malignant, 10% extraadrenal, and 10% familial. Discoveries regarding the genetic underpinnings of pheochromocytoma have challenged these old axioms, as discussed below.

Special Case: Pheochromocytoma in Pregnancy. Pheochromocytoma during pregnancy, although rare, is potentially fatal for the mother and child. When diagnosed in the antenatal period, pheochromocytoma results in 12% fetal mortality. Unrecognized pheochromocytoma or paraganglioma during pregnancy is associated with a twenty-sevenfold increase in maternal and fetal complications[34] α-Adrenergic blockade is associated with better outcomes, whereas surgery during pregnancy is not associated with clear risk reduction. Therefore, all pregnant patients with a diagnosis of pheochromocytoma or paraganglioma should be treated with α-blockade. If the diagnosis is made within the first 24 weeks of pregnancy, adrenalectomy may be considered in the second trimester, whereas surgery should be postponed until after delivery if the diagnosis is made in the third trimester.

Biochemical Diagnosis and Localization

Establishing the biochemical diagnosis of pheochromocytoma is based on the detection of elevated levels of catecholamines and their metabolites in body fluids. Measurements of 24-hour urine levels of these compounds have long been the cornerstone of biochemical testing. In 2002, measurement of free (unconjugated) metanephrines in plasma was introduced as an alternative screening tool for pheochromocytoma. Plasma free metanephrine testing carries an extremely high sensitivity, approaching 99%, and is recommended as the initial screening test. However, the specificity of plasma free metanephrine testing is 89% at best, with specificities at most laboratories likely to be in the 85% range or below. Given that pheochromocytoma is a rare diagnosis that is sought within a large pool of hypertensive individuals, false-positive test results are a major problem. It has been estimated that false-positive test results outnumber true-positive test results by as much as 30:1 when plasma free metanephrine testing is used as a principal screening tool.[35]

Therefore, the primary usefulness of plasma free metanephrine testing is to exclude pheochromocytoma when the test result is negative (Fig. 75.15). When the test result is positive, confirmatory testing with 24-hour urine levels of catecholamines and their metabolites is recommended. Many drugs and conditions are capable of confounding catecholamine-based testing, contributing further to the problem of false-positive results. These include sympathomimetics (present in many cold remedies), phenoxybenzamine (frequently initiated when suspicion for pheochromocytoma is raised), acetaminophen (which interferes with the plasma free metanephrine assay), many psychotropic drugs (notably tricyclic antidepressants), and major physical or psychological stressors. Results of tests performed during episodes of acute pain, critical illness, or urgent hospitalization may be misleading. The presence of confounding factors is extremely common in the population being screened because they represent manifestations or treatments of competing diagnoses.

The operating characteristics of catecholamine-based plasma and urine tests are listed, along with corresponding cutoff values, in Table 75.4. Cutoff values for 24-hour urine tests are deliberately set high to maximize specificity; these values are approximately double the upper 95% reference range in most laboratories. A urine collection may be considered positive if total metanephrines or any single catecholamine fraction (e.g., epinephrine, norepinephrine, and dopamine) is elevated above its cutoff value. This approach maintains high specificity and yields an acceptable sensitivity of 88%.[36] Importantly, it takes into account the fact that pheochromocytomas synthesize and metabolize catecholamines and that tumors may possess heterogeneous secretory profiles, depending on their relative expression of synthetic and degradative enzymes (see Fig. 75.6).

FIGURE 75.15 Algorithm for the diagnosis, localization, and management of pheochromocytoma. Initial plasma free metanephrine testing can effectively exclude the diagnosis if the result is negative. A 24-hour urine collection for catecholamines and their metabolites is generally performed twice, with cutoffs approximately twice the upper limit of normal being criteria for positivity (see Table 75.4). Clonidine suppression testing can be used for the small fraction of patients in whom the diagnosis remains uncertain after urine testing. Localization with computed tomography *(CT)* or magnetic resonance imaging *(MRI)* follows biochemical confirmation of the diagnosis, with metaiodobenzylguanidine *(MIBG)* scanning performed for younger patients and those otherwise at risk for multifocal disease. Phenoxybenzamine is given in escalating doses for at least 2 weeks before surgery.

Two 24-hour urine collections for catecholamines and their metabolites are sufficient to make (or to exclude) the diagnosis of pheochromocytoma in almost all cases. Clonidine suppression testing, the measurement of plasma free normetanephrine levels after the oral administration of 0.3 mg clonidine, may help clarify equivocal test results but is very rarely used. Anatomic localization may be performed with MRI or CT. MRI is slightly more sensitive, but CT often yields better anatomic definition for operative planning (Fig. 75.16). The specificity of either modality is only 70% because of the high prevalence of incidental adrenal nodules. Scintigraphy with ^{131}I- or ^{123}I-labeled metaiodobenzylguanidine (MIBG; Fig. 75.17) can be performed in select patients in whom multifocal or malignant disease is suspected. MIBG scanning is highly specific for pheochromocytoma but carries a sensitivity of only 77% to 90%. PET and PET/CT using novel radionuclides such as ^{18}F-L-dihydroxyphenylalanine (^{18}F-DOPA; Fig. 75.18) and ^{18}F-dopamine are highly sensitive and superior to MIBG scanning in the imaging of pheochromocytoma. Currently, the best PET/CT radiopharmaceutical for the localization of pheochromocytoma is ^{68}Ga-DOTATATE, which has a rate of lesion detection (97.6 %), which is higher than FDG PET/CT (49%) and ^{18}F-FDOPA PET/CT (75%).[37] However, the availability of these techniques remains confined to a small number of academic centers worldwide.

Perioperative Care

Throughout the first half of the 20th century, perioperative mortality rates in the treatment of pheochromocytoma ranged from 26% to 50%. Currently, the mortality rate in most specialty centers is approximately 1%. This dramatic improvement can largely be ascribed to advances in pharmacology, physiology, anesthesia, and perioperative medical care. The adverse perioperative hemodynamic changes most commonly observed with pheochromocytoma are intraoperative hypertension and postoperative

TABLE 75.4 Cutoff Values for Biochemical Diagnosis of Pheochromocytoma

	CUTOFF VALUE				
TEST[a]	**mol**	**g**	**DEFINITIONS**	**SENSITIVITY (%)**	**SPECIFICITY (%)**
Plasma free metanephrine	0.3 nmol/L	59 μg/L	Paired test, positive result if either or both values are elevated	99	85–89
Plasma free normetanephrine	0.6 nmol/L	110 μg/L			
Urinary total metanephrines	6.6 μmol/day	1.3 mg/day		71	99.6
Urinary epinephrine	191 nmol/day	35 μg/day		29	99.6
Urinary norepinephrine	1005 nmol/day	170 μg/day		50	99.6
Urinary dopamine	4571 nmol/day	700 μg/day		8	100
Urinary total metanephrines and catecholamines	—		Grouped test, positive result if any one of the following three urinary values is elevated: total metanephrines, epinephrine, norepinephrine, dopamine	88	99
Urinary vanillylmandelic acid	40 μmol/day	7.9 mg/day		64	95
Clonidine suppression test			Positive result = elevated level after clonidine and fall of <40	96	100
Plasma free normetanephrine	0.61 nmol/L	112 μg/L			

[a] When it is performed twice, 24-hour urine testing of urinary total metanephrines and catecholamines (grouped test) is highly sensitive and highly specific.

hypotension. Intraoperative hypertension may be caused by stimulation of catecholamine release by anesthetic induction agents as well as by direct manipulation of the tumor. Postoperative hypotension may be profound. It results from a state of chronic hypovolemia created by the presence of excess circulating catecholamines. Sudden withdrawal of this stimulus after tumor removal leads to peripheral arteriolar vasodilatation and a dramatic increase in venous capacitance, which together may precipitate cardiovascular collapse. In their early report of a large successful case series, investigators at the Mayo Clinic described the use of intraoperative α-adrenergic blockade followed by aggressive volume repletion and the administration of α-adrenergic agonists in the immediate postoperative period.[38]

The principles of perioperative care remain the same today. As soon as the biochemical diagnosis of pheochromocytoma has been confirmed, α-adrenergic blockade should be initiated to protect against hemodynamic lability. Nonselective (phenoxybenzamine) and selective (prazosin, doxazosin) α-adrenergic antagonists demonstrate similar outcomes. Our practice is to start with phenoxybenzamine 10 mg twice daily. The dosage can be titrated upward every 2 to 3 days to a maximum of 40 mg three times daily to achieve normalization of heart rate and blood pressure. The period of preoperative conditioning should last at least 10 to 14 days to allow adequate reversal of α-adrenergic receptor downregulation. This restores sensitivity to vasopressor agents, which can then be used to treat the patient postoperatively. Phenoxybenzamine is a nonspecific, noncompetitive (irreversible), long-acting (half-life of 24 hours) α-adrenergic antagonist. It is associated with side effects including postural hypotension and significant nasal congestion but provides the most complete α-blockade among available agents, and its pharmacokinetics permit serum drug levels to decay in parallel with catecholamine levels postoperatively. Calcium channel blockers may be added for patients who have inadequate blood pressure control after titration of an α-blocker. The cost and availability of phenoxybenzamine in the United States have become highly variable in recent years, making it an impractical choice for a significant number of patients. For this reason, selective α-blockers have gained popularity as the preferred medication for preoperative conditioning in some centers. Because of the possibility of increased intraoperative hemodynamic fluctuation with this approach, the experience and communication between the anesthesia and surgical teams are critical to ensure patient safety.

β-Blockers may be administered after adequate α-blockade has been achieved for the subset of patients with persistent tachycardia, who often have predominantly epinephrine-secreting tumors. β-Blockers should never be the first agent administered because a decrease in peripheral vasodilatory β-receptor stimulation results in unopposed α-adrenergic tone, which may exacerbate hypertension. Preoperative volume expansion with isotonic fluids has been advocated in the past. However, in our experience, the need for this is significantly reduced when aggressive preoperative α-blockade has been achieved because the resultant increase in venous capacitance restores euvolemia gradually by stimulating thirst. Clinical suspicion for hypovolemia should remain high in the postoperative period, and patients should be resuscitated aggressively if they become hypotensive or oliguric. Some patients may require vasopressors after tumor removal, especially if preoperative α-blockade is incomplete.

Surgical Management and Outcomes

Successful operative treatment of pheochromocytoma is dependent on close communication between the surgeon and anesthesiologist. Invasive hemodynamic monitoring is required, and fluid management must be meticulous. Manipulation of the tumor should be minimized, and the anesthetic team should be prepared to administer supplemental intravenous α- and β-blockers as well as vasopressors when necessary.

Surgery is curative in more than 90% of pheochromocytoma cases. Although these tumors are highly vascular and tend to adhere to adjacent structures (Fig. 75.19), most of them can be removed successfully by a minimally invasive approach. Minimally invasive resection is contraindicated when preoperative imaging demonstrates local invasion. Open resection should be considered for larger (>6 cm) pheochromocytomas depending on surgeon experience to prevent tumor rupture, which can lead to local recurrence even in benign cases.[39] Advances in surgical technique have resulted in reduced operative complication rates. Specifically, functional image-guided focused exploration has

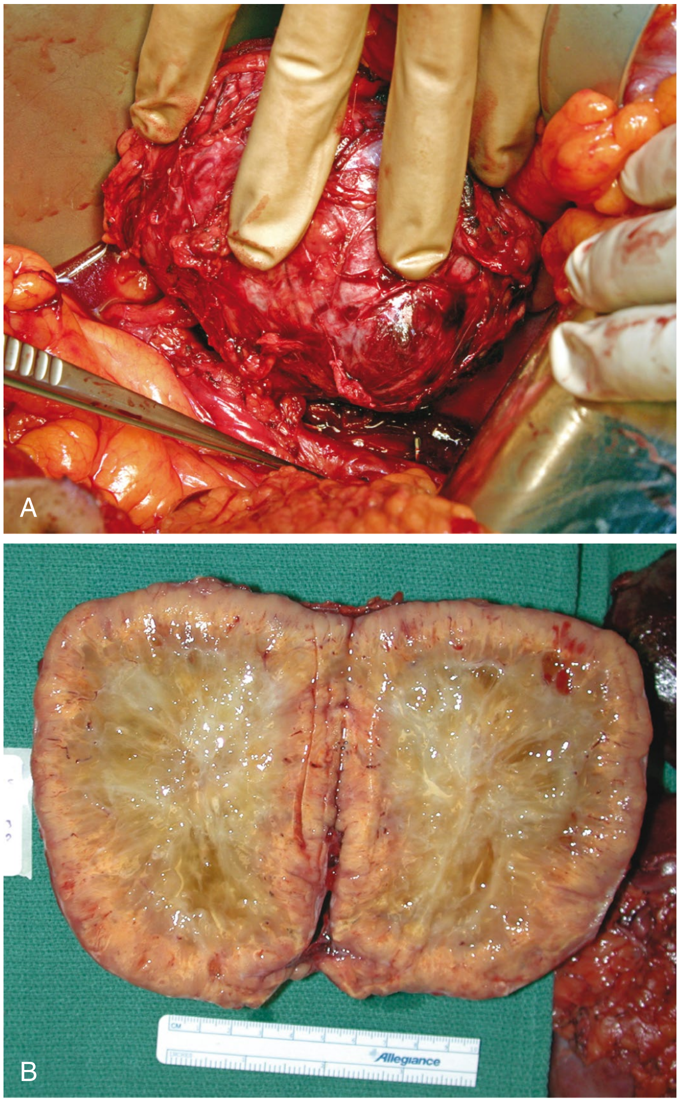

FIGURE 75.19 Gross appearance of pheochromocytoma. (A) Open resection of a left paraaortic extraadrenal pheochromocytoma (depicted in Fig. 75.17B) through an infracolic approach. The patient's head is to the right. The tumor is being rotated medially by the surgeon's hand to reveal the left ureter, indicated by forceps. (B) Left adrenal pheochromocytoma. (A, Courtesy Dr. Stan Sidhu.)

replaced bilateral adrenal and retroperitoneal exploration, leading to diminished rates of solid organ injury.

Molecular Genetics of Pheochromocytoma

Familial pheochromocytomas are much more common than previously believed. Before 2000, pheochromocytoma was known to be associated with multiple endocrine neoplasia type 2 (MEN2) syndromes (40%–50% penetrant), von Hippel-Lindau syndrome (10%–20% penetrant), and neurofibromatosis type 1 (1%–5% penetrant). Succinate dehydrogenase, which is made up of four subunits and two coassembly units, is a protein complex localized to the mitochondria and catalyzes essential steps in oxidative phosphorylation. Germline mutations in the genes encoding the succinate dehydrogenase subunits *(SDHA, SDHB, SDHC, SDHD, SDHAF2)* are causatively associated with hereditary pheochromocytoma and paraganglioma. More than 20 driver genes have been documented in pheochromocytoma and paraganglioma, and at least one-third of patients with pheochromocytoma have a germline mutation.[40] Germline genetic testing is therefore indicated for all patients with pheochromocytoma and paraganglioma. The discovery of a germline mutation may influence prognosis and surveillance, prompt additional investigations, and enable early identification of affected family members.

Familial cases are manifested at an earlier age and are more likely to be multifocal (Table 75.5). Succinate dehydrogenase B (*SDHB*) mutation carriers have high rates of extraadrenal (abdominal or thoracic) pheochromocytomas and malignant disease, whereas patients with pathogenic variants in succinate dehydrogenase D (*SDHD*) tend to present with multiple tumors and hormonally inactive paragangliomas of the head and neck. The lifetime penetrance of pheochromocytoma or paraganglioma in succinate dehydrogenase mutations is estimated at more than 75%. Cortical-sparing adrenalectomy should be considered in cases of familial pheochromocytoma where the risk of contralateral pheochromocytoma is high. Preservation of at least one-third of one adrenal gland is necessary to allow for adequate cortical function without the need for exogenous steroids.[39]

TABLE 75.5 Hereditary Syndromes Associated With Pheochromocytoma

SYNDROME	GENE MUTATION	PHENOTYPE
Hereditary leiomyomatosis and renal cell carcinoma syndrome (HLRCC)	*FH*	Leiomyomas, renal cell carcinomas
Hereditary pheochromocytoma	*HIF2A/EPAS1*	Familial polycythemia, somatostatinomas
Hereditary pheochromocytoma	*MAX*	Unknown
Neurofibromatosis type 1 (von Recklinghausen disease)	*NF1*	Neurofibromas, café au lait spots, Lisch nodules (benign iris hamartomas)
Multiple endocrine neoplasia type 2A	*RET*	Medullary thyroid cancer, primary hyperparathyroidism
Multiple endocrine neoplasia type 2B	*RET*	Medullary thyroid cancer, marfanoid habitus, mucosal neuromas
Familial paraganglioma syndrome	*SDHA, SDHB, SDHC, SDHD, SDHAF2*	Gastrointestinal stromal tumors, renal cell carcinomas
Hereditary pheochromocytoma	*TMEM127*	Renal cell carcinomas
von Hippel-Lindau	*VHL*	Retinal angioma, central nervous system hemangioblastoma, renal cell cancer, primitive neuroectodermal tumor, pancreatic and renal cysts

Metastatic Pheochromocytoma

Depending on the underlying genotype, 2.5% to 40% of pheochromocytomas will metastasize. Survival at 5 years ranges from 20% to 45% in the setting of metastatic disease.[41] No histopathologic criteria for determining metastasis have demonstrated the ability to predict the clinical course accurately. Metastasis is defined as the presence of pheochromocytoma in non-chromaffin-derived tissues to distinguish metastatic disease from multifocal primary tumors. The most common sites of metastasis are the axial skeleton, lymph nodes, liver, lung, and kidney. Treatment of primary and recurrent disease centers on surgical resection, which, even in the absence of cure, may have significant palliative benefits in terms of managing mass effect in critical anatomic locations and reducing the systemic impact of catecholamine excess.[42]

Metastatic pheochromocytomas are minimally responsive to radiotherapy and conventional chemotherapy. ^{131}I-MIBG radionuclide therapy achieves a complete or partial response rate of 22% in select patients with metastatic pheochromocytoma.[43] Peptide receptor radioligand therapy with ^{177}Lu-DOTA-SSA is widely used in Europe for metastatic disease but remains in clinical trial status in the United States. Chronic medical management of catecholamine excess should be performed with α_1-adrenergic selective blockers because of their favorable side effect profile. No targeted therapies exist yet for metastatic disease.

Incidentally Discovered Adrenal Mass (Incidentaloma)

Epidemiology and Differential Diagnosis

Incidentally discovered adrenal masses, also termed *incidentalomas,* are discovered through imaging performed for unrelated disease. Their existence as a clinical entity is a byproduct of advanced medical imaging. Incidentalomas were first described in the early 1980s, when CT scanners became more prevalent in developed nations, and they have become a common clinical problem as the use of CT and MRI has become widespread. Incidentalomas have been found in up to 8% of autopsies and approximately 4% of abdominal imaging studies. The prevalence increases to as high as 10% in patients older than 60 years.[44]

The differential diagnosis of adrenal incidentaloma is broad and includes secreting and nonsecreting neoplasms (Fig. 75.20). In patients with a history of malignant disease, metastatic disease is the most likely cause of adrenal masses (see later, “Metastases to the Adrenal Gland”). In patients without a clear history of malignant disease, at least 80% of incidentalomas are nonfunctioning cortical adenomas or other benign lesions that do not require surgical management. Thus, in most patients, the most important aspect of management is to identify the subset of adrenal masses that are likely to have a clinical impact.

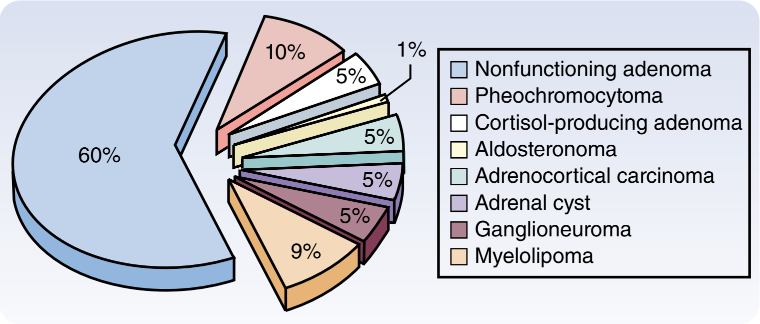

FIGURE 75.20 Differential diagnosis of adrenal incidentaloma in patients without a history of malignant disease. Approximate proportions of the various pathologic processes are shown.

Clinical Evaluation and Surgical Management

The evaluation of the adrenal incidentaloma integrates hormonal evaluation with size criteria. The principles and methods of hormonal evaluation have been discussed in the tumor-specific sections (see earlier) and are generally applicable to incidentalomas.

Evaluation begins with history taking, with a focus on prior malignant disease, hypertension, and symptoms of glucocorticoid or sex steroid excess. Biochemical investigations for hormonally active tumors are followed by consideration of size criteria (Fig. 75.21). In a general sense, surgery is recommended for hormonally active tumors and those that carry a significant risk of malignancy. ACCs represent less than 2% of adrenal tumors measuring 4 cm or smaller and roughly 6% of those measuring 4 to 6 cm. Tumors larger than 6 cm carry a more than 25% risk of malignancy. Because CT and MRI underestimate adrenal tumor size by approximately 20%, an effect that is exaggerated in smaller tumors, our practice is to remove all incidentalomas measuring 4 cm or larger in low-risk surgical patients. We strongly consider removal of those measuring 3 to 4 cm, particularly in younger patients who wish to avoid the burden of surveillance imaging.

Factors that should be considered in surgical decision-making for this latter group include suspicious imaging characteristics, the patient's age and surgical risk, growth on interval imaging, and the patient's preference. Characteristics suggestive of a benign lesion on CT scan include homogeneous appearance, well-defined borders, high lipid content, rapid washout of contrast material, and low degree of vascularity. Features that are concerning for malignancy include irregular or ill-defined borders, necrosis, internal calcifications or hemorrhage, and high vascularity. ^{18}F-FDG PET is usually reserved for suspicious cases and has high sensitivity and specificity for distinguishing between benign and malignant adrenal lesions, although it cannot differentiate between a metastasis and primary ACC. If observation is chosen, patients should undergo repeated imaging in 6 to 12 months and then on an annual basis for several years, given the fact that 5% to 25% of adrenal masses may increase in size.

It must be emphasized that CT-guided biopsy is rarely helpful in the evaluation of adrenal masses and may be hazardous. The diagnosis of primary adrenal malignancy cannot reliably be established based on cytologic criteria alone. Therefore, the use of adrenal biopsy is generally confined to patients with a history of extraadrenal malignancy in whom a tissue diagnosis would be anticipated to change management.[45] In all cases, pheochromocytoma must be excluded before attempting such a procedure to avoid precipitating a potentially fatal hypertensive crisis.

As with the other disease processes that have been discussed, most adrenal incidentalomas can be removed via a minimally invasive approach, except for those displaying obvious malignant features on imaging. No upper size limit to this approach has been established, and tumors measuring 15 cm have been successfully removed by experienced surgeons using a minimally invasive approach.

Metastases to the Adrenal Gland

Epidemiology and Clinical Features

The adrenal glands are common sites of metastasis because of their rich vascular supply. Autopsy studies have revealed that approximately 25% of patients with carcinomas eventually develop adrenal involvement. In 50% of these cases, metastatic disease is bilateral. The primary cancers that most often spread to the adrenals are those of the lung, gastrointestinal tract, breast, kidney, pancreas, and skin (melanoma). Patients with isolated adrenal metastases represent a very small subset of the total. However, these individuals are of particular interest to the surgeon and oncologist because resection of isolated adrenal metastases may improve survival, particularly in conjunction with systemic therapy.

Clinical Evaluation and Surgical Management

Evaluation of patients presenting with isolated adrenal metastases must involve careful exclusion of extraadrenal disease with CT or MRI (including the head in cases of breast cancer or melanoma and triphasic contrast-enhanced CT evaluation of the liver plus 3-mm slices through the lungs for gastrointestinal malignant neoplasms) as well as bone and PET scans, when appropriate. Patients presenting with isolated bilateral adrenal metastases (Fig. 75.22) must be evaluated for adrenal insufficiency because of replacement of all normal adrenal tissue with tumor, which may occur in up to 30% of these patients. This is best performed with measurement of morning cortisol and ACTH levels. Cortical insufficiency should be adequately treated before operation to avoid perioperative adrenal crisis.

Most adrenal metastases are well encapsulated and are thus amenable to minimally invasive resection; however, significant fibrosis may be observed in metastatic disease, particularly tumors that have previously been treated with local radiation therapy. Complete adrenal metastasectomy has yielded mean survival rates of up to 3 years compared with 12 months for patients undergoing incomplete resection and 6 months for patients not undergoing surgical therapy.[46]

Adrenalectomy

FIGURE 75.21 Algorithm for the management of an adrenal incidentaloma. Adrenalectomy is recommended for all patients with functional tumors. For nonfunctioning tumors, the risk for malignancy is assessed according to size. Tumors larger than 5 cm on computed tomography carry a more than 25% risk for malignancy and need to be removed. Those smaller than 3 cm can be safely observed. Case-specific factors must be considered for intermediate-sized tumors. *CT,* Computed tomography; *PAC,* plasma aldosterone concentration, in ng/dL; *PRA,* plasma renin activity, in ng/(mL • hr).

TECHNICAL ASPECTS OF ADRENALECTOMY

Choice of Operative Approach

Because the adrenal glands are medial and posterior structures, conventional open surgery requires large incisions for adequate exposure. Minimally invasive approaches to adrenalectomy, however, greatly decrease length of hospitalization, pain, and operative blood loss and have a lower rate of postoperative complications such as hernia and wound infection. Similar degrees of benefit are observed with laparoscopic transabdominal and posterior retroperitoneoscopic approaches. One randomized controlled trial demonstrated reduced postoperative pain and faster recovery after the posterior retroperitoneoscopic approach.[47] We currently employ both techniques and favor the retroperitoneoscopic approach for tumors smaller than 6 cm, for bilateral tumors, and in patients with a history of extensive prior abdominal surgery. The retroperitoneoscopic approach is more challenging in older, obese male patients because of increased retroperitoneal fat, making initial entry and orientation more difficult. Severe obesity (body mass index >35) results in compression of the retroperitoneum by the abdominal viscera when the patient is in the prone position and is a relative contraindication to the retroperitoneoscopic approach, depending on the surgeon's experience. The lateral transabdominal technique offers a wider operative field and greater versatility, and it is well suited for larger tumors and obese patients. The overall conversion rate to open adrenalectomy is less than 5% with either technique in large series.[48]

As noted, open adrenalectomy should be considered for primary adrenal tumors demonstrating features suggestive of malignancy, such as large size (>8 cm), clinical feminization, hypersecretion of multiple steroid hormones, or any of the following imaging attributes: local or vascular invasion, regional adenopathy, and metastases. For open adrenalectomy, many approaches can be used for adequate exposure (see later).

Laparoscopic Lateral Transabdominal Adrenalectomy

Patient Preparation and Positioning

Draw sheets and a full-length beanbag are placed on the operating table in advance. It is important that the table be capable of flexion, and occasionally a kidney rest can be used. The patient is initially positioned supine for induction of anesthesia and placement of a urinary catheter. Intermittent pneumatic compression devices are applied to the legs. The placement of an orogastric or nasogastric tube for gastric decompression is frequently helpful, particularly in treating left-sided lesions. We routinely have large-bore IV access and blood available for both right- and left-sided adrenal operations (though it is rarely needed). The patient is then turned on the side (80-degree lateral decubitus position), with the side of the lesion facing upward (Fig. 75.23). At this point, the patient is carefully positioned so that the 10th rib is directly over the break point in the table. The table is flexed and the beanbag rigidified in a position that supports the buttocks and back while leaving the umbilicus, an important surface landmark, exposed. Flexing the table and raising the kidney rest serve to widen the space between the costal margin and iliac crest and to drop the iliac crest away from the plane of the laparoscopic instruments. Wide cloth tape is used to secure the patient to the table at the chest, hips, and lower extremities. Great care must be taken to protect bone prominences and points of potential peripheral nerve compression in the extremities (e.g., peroneal nerve). The surgical preparation is carried from the nipple line to the pubis and from the umbilicus to the midline of the back. It is essential to prep while considering the need for conversion to open surgery, if required.

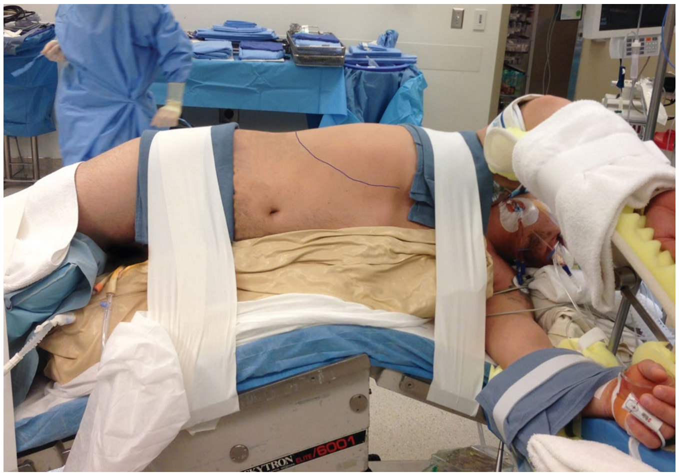

FIGURE 75.23 Positioning of the patient for left lateral transabdominal laparoscopic adrenalectomy.

Careful positioning is essential for technical success in laparoscopic adrenalectomy. As will be discussed, the surgeon is reliant on gravity to serve as a retractor for providing the necessary exposure. Having the patient securely fixed to the table permits the often extreme positioning with respect to pitch (Trendelenburg, reverse Trendelenburg) and roll (tilting left, right) that is necessary during the operation.

Technique

Left adrenal. Initial peritoneal access is achieved 2 cm inferior to the costal margin in the midclavicular line (Palmer point). This can be performed with the Veress technique or using an optical trocar in most cases. We generally use four radially dilating trocars. The ports are equally distributed along the costal margin, with the posterior port placed as far lateral-posterior as permitted by the position of the colon (Fig. 75.24). It is advisable to leave at least 5 cm (four fingerbreadths) between each port to minimize external interference of the laparoscopic instruments. For tissue dissection, we employ the hook monopolar cautery and an energy-based tissue sealing or dividing device.

The lateral attachments of the spleen are taken down first, with the goal of rotating the left upper quadrant viscera anteromedially. Great care must be taken to avoid a capsular tear of the spleen. It is essential to not rush this step, as a bleeding spleen capsule will be a nuisance throughout the operation and will distort the natural coloration of tissue planes. Splenic mobilization is continued until the greater curvature of the stomach becomes visible at its apex, at which point the spleen and tail of the pancreas are allowed to fall anteriorly with rightward tilting of the table and gentle use of the fan retractor, if necessary. It is critical to achieve the correct plane of dissection precisely during this part of the procedure because the tail of the pancreas and splenic vessels are potentially vulnerable to injury. At this point, the left adrenal gland and the left kidney are under/posterior to Gerota's fascia. The spleen and pancreas are both anterior to Gerota's fascia. Thus, it is *essential* to dissect underneath Gerota's fascia when looking for the adrenal gland. In patients with large or inferiorly positioned tumors, the splenic flexure of the colon must be mobilized

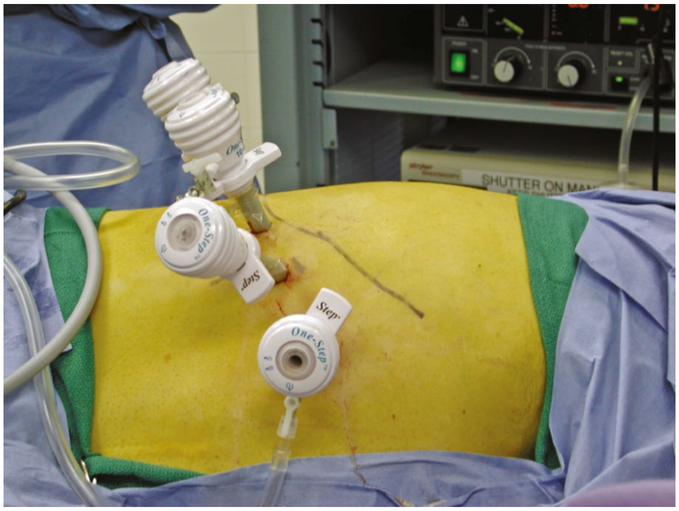

FIGURE 75.24 Port placement for right laparoscopic adrenalectomy. The patient is lying right-side up, with the head toward the right. The *marked line* denotes the costal margin. Ports are placed approximately 2 cm inferior to the costal margin, spaced about four fingerbreadths apart.

caudally by dividing the splenocolic ligament. We use an open book technique, which involves developing the cleftlike plane just medial to the adrenal gland and lateral to the aorta (Fig. 75.25). The left-hand page of the book is composed of the spleen, tail of the pancreas, and greater curvature of the stomach (everything anterior to Gerota's fascia). The right-hand page of the book is made up of the kidney and adrenal tumor. The left crus of the diaphragm is a useful landmark that leads the surgeon to the left inferior phrenic vein.

As mentioned in the anatomy section of this chapter, the left inferior phrenic vein courses along the medial aspect of the left adrenal gland before joining with the left adrenal vein. By developing the cleft of the open book, moving from superior to inferior, the adrenal vein is encountered at the inferomedial aspect of the adrenal gland. The small adrenal arteries that lie within this plane can be handled with energy-based coagulation. The left adrenal vein is carefully dissected out, coagulated or clipped, and divided. The inferior tip of the left adrenal gland may extend caudally, approaching the renal hilum within millimeters. However, because the left adrenal vein is rather long (2 cm), it is generally not necessary to expose the renal vasculature during left adrenalectomy. Many patients have a superior pole renal artery branch that approaches the inferior aspect of the left adrenal gland. Injury to this structure must be carefully avoided by keeping dissection close to the adrenal capsule while the specimen is elevated away from the medial aspect of the superior pole of the left kidney. Also, it is essential to study the CT or MRI preoperatively to look for supernumerary and accessory renal arteries.

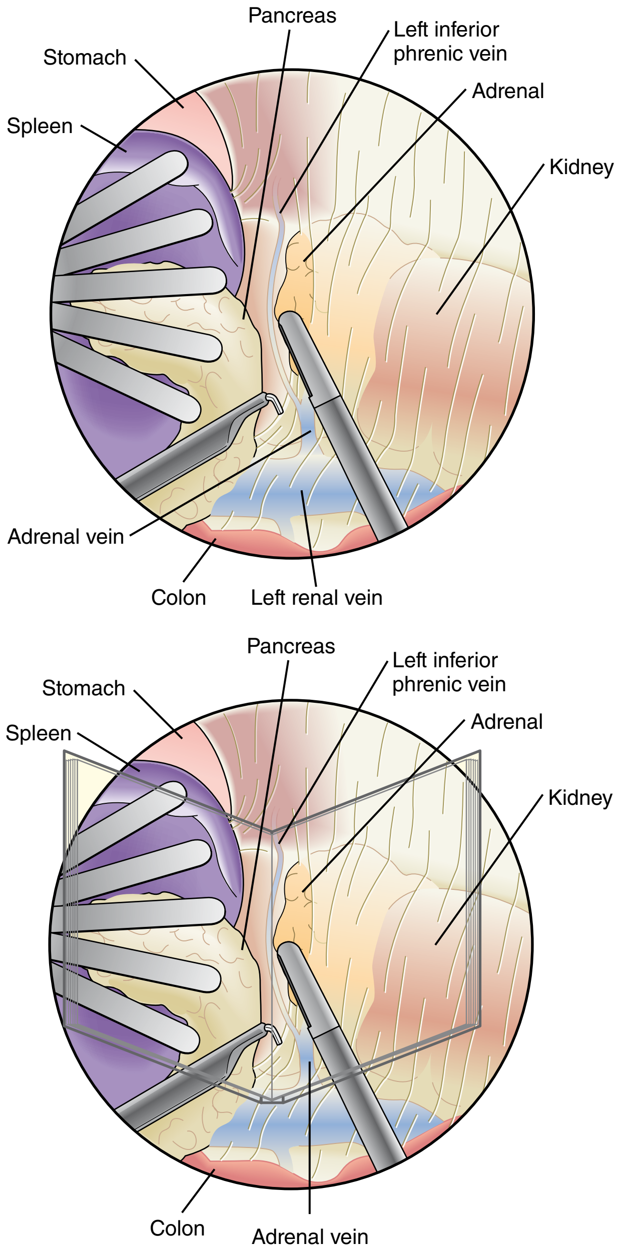

FIGURE 75.25 Technique of left laparoscopic adrenalectomy. The spleen and pancreatic tail have been mobilized and retracted anteromedially to expose the adrenal gland. The cleft of the open book is developed in a superior-to-inferior direction to identify the inferior phrenic vein and adrenal vein.

The adrenal gland is liberated by completing dissection circumferentially and posteriorly, separating the specimen from the superior pole of the kidney and posterior abdominal wall. These attachments are deliberately divided last because they aid in suspending the adrenal gland on the lateral-superior wall of the operative field, providing exposure of the medial vascular plane during the critical initial portion of the procedure. The tumor is placed into a resilient catchment device and extracted. Tumor morcellation can be considered if it is known to be benign but should never be performed if the mass is potentially ACC. If noncutting trocars are used, only the skin will need to be closed.

Right adrenal. Laparoscopic right adrenalectomy is, in some respects, a mirror image of the procedure just described. During right adrenalectomy, the left-hand page of the open book is made up of the kidney and adrenal tumor and the right-hand page is composed of the bare area of the liver (Fig. 75.26). To gain access to the appropriate plane, the right triangular ligament of the liver must first be completely mobilized and the liver allowed to rotate anteromedially. On the right side, the colon usually lies well inferior to the operative field. When

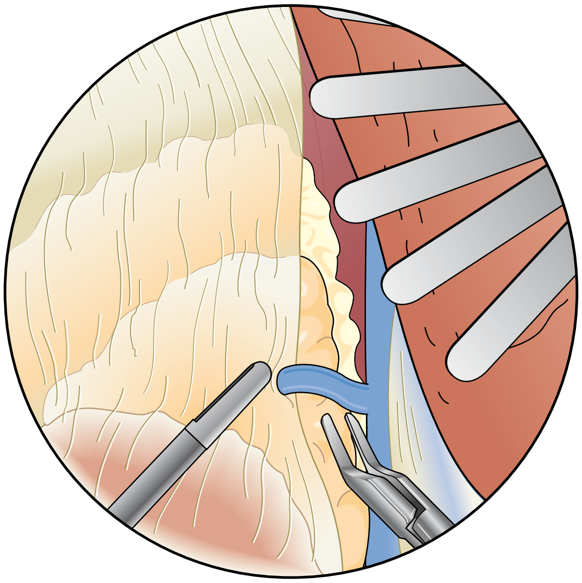

FIGURE 75.26 Technique of right laparoscopic adrenalectomy. The liver has been mobilized and retracted medially to expose the adrenal gland and inferior vena cava. The space just medial to the adrenal gland is developed to identify the adrenal vasculature.

developing the space between the adrenal gland and inferior vena cava from superior to inferior, the surgeon must be mindful of adrenal vein variants, as illustrated in the anatomy section of this chapter (see Fig. 75.3). The right adrenal vein is a potentially perilous structure to manage because it is short, wide, variable, and confluent, with thin-walled, large-capacitance vessels (the inferior vena cava in more than 80% of cases, followed by the renal vein, and, uncommonly, the right hepatic vein) that can bleed briskly if directly injured (e.g., by the cautery), lacerated from undue traction on adjacent structures, or sheared by clips. A significant second adrenal vein may be found in up to 10% of patients. By methodically dissecting one layer at a time and moving from superior to inferior, all potential adrenal vein variants can be encountered in a controlled fashion (Fig. 75.27). The adrenal vein must be dissected out delicately, definitively ligated, and then divided. Loss of control of the adrenal vein stump should be avoided; should this occur, conversion to an open procedure may be necessary.

Of note, the junction of the inferior vena cava and right renal vein is frequently difficult to identify. In vivo, the transition is a gradual curve rather than the 90-degree takeoff depicted in anatomy texts. Therefore, it cannot be used as a reliable anatomic landmark for identification of the adrenal vein. After control of the vein, the remaining mobilization of the right adrenal gland is straightforward because the inferomedial limb generally does not reach as far down toward the renal hilum as on the left side.

Posterior Retroperitoneoscopic Adrenalectomy

Posterior retroperitoneoscopic adrenalectomy was popularized in 1994 by Walz and associates.[49,50] The retroperitoneal approach has several advantages, including avoidance of mobilization of the solid organs that is necessary with transabdominal approaches, elimination of the need for repositioning during bilateral adrenalectomy, and avoidance of anterior adhesions in patients with extensive prior abdominal surgery. One disadvantage is the relatively small working space, which makes the retroperitoneal technique best suited for tumors smaller than 7 cm in diameter.

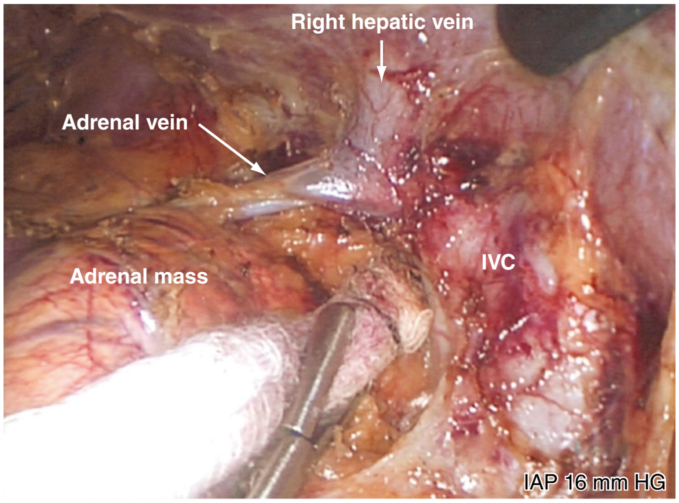

FIGURE 75.27 Right adrenal vein variant. This solitary adrenal vein arises from the superior apex of the gland and drains into the confluence of the inferior vena cava *(IVC)* and right hepatic vein, as shown in Fig. 75.3F.

A prone position is used, with supports placed under the lower chest and pelvic girdle so that the abdomen is allowed to hang anteriorly (Fig. 75.28A). Three ports are placed inferior to the 12th rib (see Fig. 75.28B) using a direct cut-down technique for initial access. Relatively high insufflation pressures of 20 to 28 mm Hg are used and have caused no complications in regard to air emboli, hypercapnia, or clinically significant soft tissue emphysema. The working space is initially created by bluntly dissecting the retroperitoneal contents anteriorly away from the ports. The upper pole of the kidney is mobilized and reflected inferiorly to expose the adrenal gland. Mobilization of the adrenal gland begins near the crus of the diaphragm, at the inferomedial aspect of the gland. This is where the left adrenal vein is almost always encountered early in the procedure (Fig. 75.29A). On the right side, the vein is encountered slightly later as dissection proceeds superiorly (see Fig. 75.29B). The small adrenal arteries that run within the medial vascular space are coagulated. After the superior apex of the adrenal gland is mobilized, dissection proceeds circumferentially to include the periadrenal fat.

Complications and Postoperative Care

Potential technical complications of minimally invasive adrenalectomy include venous hemorrhage and bleeding from solid organ capsular injuries. Small amounts of bleeding can often be managed with coagulation or direct pressure using a rolled Kittner gauze. Hollow viscus injuries are uncommon but may be associated with procedures performed in patients with prior major

abdominal surgery. Pancreatic injuries and fistulas have been reported with left-sided procedures; these are rare complications, as are port site hernias and port site metastases in cases of malignant disease. Violation of the tumor capsule and tumor spillage can lead to tumor recurrence, especially in the case of pheochromocytoma. Patients undergoing minimally invasive adrenalectomy for Cushing syndrome are at risk for surgical site infections because of their catabolic and immunosuppressed state. These include port site infections in 5% of patients and, rarely, subphrenic abscesses requiring catheter drainage. One complication specific to the retroperitoneal approach is injury of the subcostal nerve causing relaxation or hypoesthesia of the abdominal wall, which occurs in 8% of cases and is usually temporary.

Patients who undergo minimally invasive adrenalectomy recover rapidly. Most patients, including those treated for pheochromocytoma and Cushing syndrome, can leave the hospital on the first postoperative day. In the treatment of adrenal tumors, successful outcomes hinge on excellent perioperative medical management as much as technical skill, particularly in cases of pheochromocytoma and Cushing syndrome, as discussed.

Open Anterior Transabdominal Adrenalectomy

Patient Preparation and Positioning

An epidural catheter or local injection with liposomal bupivacaine may be used for pain control for open adrenal surgery. The patient is positioned supine, with the ipsilateral side slightly elevated on a bolster (Fig. 75.30). A urinary catheter, orogastric or nasogastric tube, and intermittent pneumatic compression devices are placed. The surgical preparation is carried from the nipple line to the pubis and down to the table on either side. Operative exposure involves trade-offs, and we prefer to customize the incision with several factors in mind. The most important of these relate to the size of the tumor and the size of the patient. For thin patients with large tumors, a midline approach from xiphoid to pubis is preferred. It provides outstanding exposure and preserves the rectus abdominus and oblique muscles. This approach is especially important for patients with professions that require physical labor (e.g., construction, plumbing). For patients with high visceral fat and more rotund abdomens, we prefer a large subcostal incision, which can extend bilaterally for better exposure. Other exposures such as thoracoabdominal or modified Makuuchi can be employed in specific circumstances.

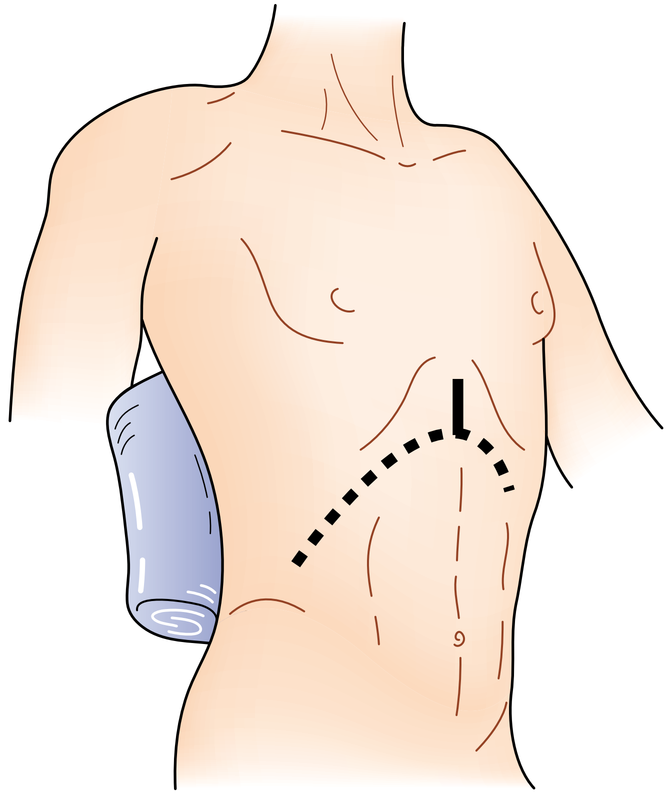

FIGURE 75.30 Positioning of the patient for open right adrenalectomy.

Technique

Left adrenal. A left adrenal mass can be approached in the same way as was described in the laparoscopic approach. This method aims to preserve the spleen and tail of the pancreas. However, many large left-sided adrenal masses are tethered by the pancreas and the spleen is stuck posteriorly, which makes it vulnerable to capsular tears. In these cases, we begin with complete splenic flexure mobilization of the colon, entering the lesser sac, and then dividing the tail of the pancreas along with the splenic artery and vein in order to gain access to the medial portion of dissection along the left diaphragmatic crus.

Right adrenal. Open right adrenalectomy begins with complete mobilization of the right lobe of the liver, including the lateral attachments and the falciform ligament. The adrenal can be exposed by rotating the liver medially or, more commonly, retracting the inferoposterior segments using long padded retractors (liver, renal vein, Deaver, or Harrington types). The retroperitoneum is entered by performing a Kocher maneuver (Fig. 75.31), and the inferior vena cava is exposed by medial reflection of the duodenum. The plane between the adrenal gland and inferior vena cava is developed first. Vascular structures, which may be numerous in highly angiogenic tumors, are ligated sequentially. The adrenal vein is isolated, securely tied, and divided. Loss of control of the adrenal vein stump may be managed with the application of a side-biting (Satinsky) vascular clamp. As noted, open adrenalectomy is generally performed in cases of suspected or known malignant disease (Fig. 75.32). Locally invasive right-sided adrenal tumors can be challenging to manage, given their frequent invasion of adjacent venous structures (Fig. 75.33A). It is our practice to involve an experienced vascular or liver surgeon in the management of tumors with extensive venous invasion. Locally invaded organs, most commonly the kidney, should be resected en bloc with the primary mass. Complete radical resection is a critical determinant of survival in patients with malignant adrenal tumors; in some cases, this can be achieved only if immediate venous reconstruction is performed (see Fig. 75.33B).

Complications and Postoperative Care

Technical complications of open adrenalectomy include venous hemorrhage, tumor embolization in cases with intravascular tumor extension, and solid-organ injury. Postoperative complications are similar to those associated with other major abdominal procedures. Most patients experience return of bowel function within 3 to 4 days and are able to leave the hospital on postoperative day 5 to 7.

ACKNOWLEDGMENT

The current authors, Heather Wachtel and Matthew Nehs, have updated and edited this version of the chapter from a previous version that was edited by Michael Yeh, Masha Livits, and Quan Yang Duh.

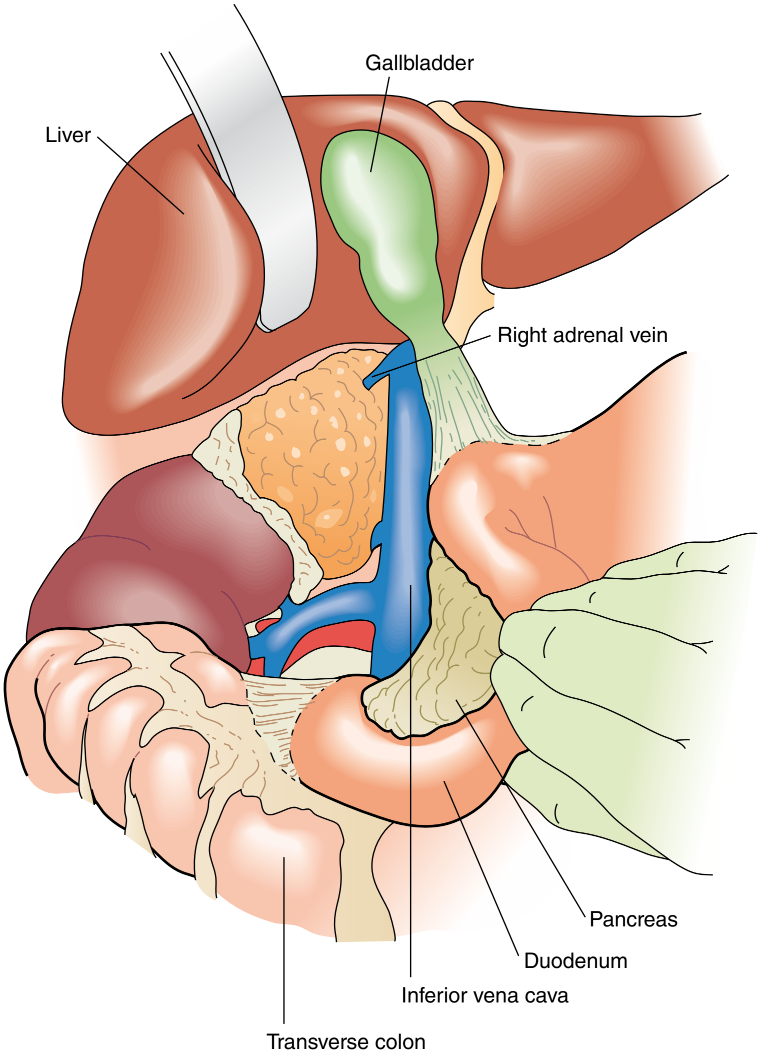

FIGURE 75.31 Open right adrenalectomy. The right lobe of the liver and the hepatic flexure of the colon have been completely mobilized. The retroperitoneum is entered, and the duodenum and head of the pancreas are reflected medially (Kocher maneuver) to expose the adrenal gland and inferior vena cava.

Medical Therapy for Pancreatic Endocrine Tumors
Outcomes
Surveillance and Follow-Up

INTRODUCTION

The German pathologist Paul Langerhans first described endocrine islet cells of the pancreas in 1869, and in 1902, Albert Nicholls reported a tumor of these islet cells.[1] Throughout the 20th century, clinical syndromes of hormonal excess from carcinoma-like "carcinoids" and different types of "islet cell tumors," including insulinomas, gastrinomas, VIPomas, and others, were identified and their associated hormones described.[2,3] Autosomal dominant genetic syndromes that include islet cell tumors as prominent features, such as multiple endocrine neoplasia type 1 (MEN1) and von Hippel-Lindau (VHL), were recognized and their responsible genes identified.[4,5] Although these tumors may be associated with clinical syndromes that include hormone production consistent with endocrine islet cell origin, contemporary research indicates that pancreatic neuroendocrine tumors (PNETs) likely arise from pluripotent stem cells in the pancreatic ductal or acinar system.[6] Unlike the more common and aggressive pancreatic ductal adenocarcinomas, PNETs usually show less aggressive behavior and exhibit distinct genetic alterations. Improved pancreatic imaging has led to increased diagnosis of nonfamilial neuroendocrine tumors that do not produce hormone excess. Indeed, it is now clear that these sporadic, nonfunctional PNETs represent the majority (90%) of neuroendocrine tumors of the pancreas.[7–9] The mainstay of PNET treatment remains surgical resection, which achieves excellent survival outcomes in localized disease. Increasingly, it is appreciated that low-grade, small tumors <2 cm may often be safely observed with minimal risk of growth or metastasis.[10,11] Localized functional tumors, those greater than 2 cm, and those with higher-risk features such as grade 2 tumors should generally be considered for resection. In metastatic tumors, resection of the primary tumor and cytoreduction of metastases can control symptoms in functional tumors and potentially increase survival in nonfunctional tumors. For advanced, unresectable, or metastatic high-grade disease, hormonal therapies like somatostatin analogues (SSAs), targeted kinase inhibitors, chemotherapy, and peptide receptor radionuclide therapy (PRRT) may delay progression and improve quality of life.

EPIDEMIOLOGY

Neuroendocrine tumor (NET) incidence of all sites steadily increased by 6.4-fold from the late 20th to early 21st century. Although still less common than lung, small bowel, and rectal NETs, PNETs now show an age-adjusted incidence in the United States of around 0.82 per 100,000 person-years. This remains much lower than the incidence of pancreatic adenocarcinoma (13.3 per 100,000), but it has increased from 0.2 per 100,000 in 1985 to 0.5 in 2000 and continues to rise.[7] Increased detection owing to higher sensitivity and use of cross-sectional imaging surely accounts for some of this, and early-stage disease shows the greatest increase in incidence.[12] Additional factors contributing to rising PNET diagnoses remain unknown. Similarly increased PNET incidence has been reported in Canada, Europe, Australia, and Asia.[13-18] In distinction from adenocarcinomas, PNETs tend to grow slowly and survival is relatively long (median nearly 100 months even with regional nodal metastases), contributing to a prevalence of 0.003% in the population, representing nearly 10% of all patients with pancreatic malignancy.[7,19]

As with other NETs, PNET incidence increases with age. Median age at diagnosis is in the late sixth decade of life,[17,20] and incidence is 0.5 per 100,000 among 40-year-olds compared with 2.5 per 100,000 among 70-year-olds.[21] Incidence may be higher among Black Americans, with rates reported to be 25% to 100% higher compared with Whites,[7,15,22] although others have reported no difference after adjustment for confounders.[21] Females are less likely to develop PNETs (45%/55% female/male distribution).[21]

Between 5% and 15% of PNETs arise in association with an autosomal dominant hereditary syndrome, depending on the population studied (Table 76.1). In a series of 383 resected PNETs, 6% of patients had a known hereditary syndrome, a number that rose to 16% among those diagnosed before age 50. Of the known hereditary syndromes, MEN1 was most common,

TABLE 76.1 Hereditary Syndromes Associated With Pancreatic Neuroendocrine Tumors

SYNDROME	RISK OF PNET	GENE	OTHER ASSOCIATIONS
MEN1	60%–80%	*MEN1* Ch11q13	Parathyroid hyperplasia; pituitary adenomas; thymic carcinoids; adrenal adenomas; lung carcinoid
VHL	5%–17%, up to 40% with some mutations	*VHL* Ch3p25-26	Cerebellar and spinal hemangioblastomas; renal cell carcinoma; endolymphatic sac tumors; pheochromocytoma; pancreatic cysts; retinal angiomas
NF1	0%–10%	*NF1* Ch17q11	Café au lait spots; freckles in skin folds; multiple neurofibromas/schwannomas of peripheral nerves; pheochromocytoma; scoliosis; meningiomas; acoustic neuromas/hearing loss; Lisch nodules in iris
TSC	1%	*TSC1* 9p34 *TSC2* 16p13	Hamartomas of multiple organs (heart, lungs, kidneys, lymphatics, eyes, brain); neurologic problems; skin lesions (fibromas, focal hypopigmentation)
Cowden syndrome	Case reports	*PTEN* 10q23	Hamartomas and cancers of the breast, thyroid, uterus, colorectum, kidney, and skin; trichilemmoma; macrocephaly

MEN1, Multiple endocrine neoplasia type 1; *NF1,* neurofibromatosis type 1; *PNET,* pancreatic neuroendocrine tumor; *TSC,* tuberous sclerosis; *VHL,* von Hippel-Lindau.

followed by VHL (65% and 26%, respectively).[20] Pancreatic microadenomas represent one of the "three Ps" of MEN1 (with four-gland parathyroid hyperplasia and pituitary tumors being the others). Patients with MEN1 tend to develop multiple tumors. Nearly 100% of patients develop pancreatic microadenomas (<0.5 cm) by age 50, and larger tumors develop in around 75% of patients, with penetrance increasing with age.[23] Many of these tumors are nonfunctional, but around half of patients with MEN1 develop gastrinomas (residing in either the pancreas or duodenum), and 20% may develop pancreatic insulinomas.[23] In addition to thymic neuroendocrine neoplasms, metastatic PNETs rank among the most common causes of disease-specific death in MEN1.[24,25]

VHL syndrome is autosomal dominant and results in failure of VHL protein to promote degradation of hypoxia-inducible factor (HIF), leading to constitutive HIF activation and development of multiple tumors.[26] Nonfunctional PNETs occur in around 20% of patients with VHL, at a median age in the mid-30s, and arise less commonly than cystic pancreatic lesions (~50%). Relative frequencies of PNETs versus other VHL manifestations such as central nervous system hemangioblastomas, renal cell carcinomas, retinal hemangiomas, pheochromocytomas, and cystic pancreatic lesions vary depending on the subtype of VHL disease and specific mutation present.[27] Type I VHL arises from truncation mutations or exon deletions and carries a lower risk of PNET (10%), whereas type II disease from missense mutations has a higher risk of developing PNETs of nearly 40%.[28]

Other hereditary syndromes associated with PNETs include tuberous sclerosis (TSC) and neurofibromatosis type 1 (NF1). In TSC, patients develop hamartomas of many organs, and PNETs are an uncommon manifestation, occurring in 1% of patients.[26] Most patients with TSC developing PNETs have mutations in *TSC2* as opposed to *TSC1.* In NF1, characterized by multiple benign neurofibromas, café au lait skin spots, and increased risk of gliomas, leukemia, and pheochromocytoma, around 10% of patients develop PNETs.[23,26] Mutations inactivating the TSC1/TSC2 protein complex or NF1 lead to loss of inhibition of mammalian target of rapamycin (mTOR) signaling and PNET development.[23] The gene responsible for Cowden syndrome, *PTEN,* also inhibits mTOR signaling. Although *PTEN* mutations sometimes exist in sporadic PNETs, and PNETs have been reported in Cowden syndrome, they remain an uncommon site of disease in these patients.[29,30]

Genetic testing for these syndromes should be performed in first-degree relatives of known patients. In MEN1 and VHL, disease features often develop in children, and testing should occur as early as possible.[11,27,31] Screening for PNETs in VHL should commence by age 15, as PNETs have developed in patients in their early teens.[31] For those without a known germline/familial diagnosis, testing for MEN1 and VHL should be considered in patients with other manifestations of these syndromes (especially hypercalcemia), those with a suggestive family history, those developing PNETs at a young age, or those with multifocal tumors. Genetic diagnoses facilitate screening for associated conditions, such as hyperparathyroidism in MEN1 and pheochromocytoma in VHL, before planning pancreatic intervention and adherence to syndrome-specific guidelines for screening for other disease manifestations.[32,33] Additionally, the unique behavior of PNETs in these syndromes affects surgical decision-making, as detailed later.

GRADE AND STAGE

Grade and stage are the most important prognostic features for PNETs. Historical series and current national databases tend to capture grade based on cellular differentiation alone. More recently, the Ki-67 index, or percentage of cells undergoing mitosis as determined by immunohistochemical (IHC) staining, has superseded differentiation as the key determinant of NET grade, and this is the single clinical parameter most indicative of a PNET's likely behavior and clinical course.[11,34] As set out in the 2004 World Health Organization (WHO) classification of endocrine tumors and updated most recently in 2022, the revised WHO grading of NETs separates them into grade 1 (<3% staining), grade 2 (3%–20% staining), and grade 3 (>20% staining), with grade strongly corresponding to differential survival.[3,34,35] Analyses of large European and American series found that grade 1 PNETs have a 5-year survival of 75% to 90%, compared with 62% to 63% in grade 2 and 7% to 12% in grade 3.[9,36] Around 90% of PNETs are grade 1 to 2, with 10% showing high-grade (grade 3) features at diagnosis.[9] An additional important distinction among grade 3 tumors is whether they have a well-differentiated histologic appearance (referred to as *G3 NETs*), as compared with

From Rindi G, Mete O, Uccella S, et al. Overview of the 2022 WHO classification of neuroendocrine neoplasms. *Endocr Pathol.* 2022;33(1): 115-154; Lloyd RV, Osamura RY, Klöppel G, Rosai J. *Classification of Tumours of Endocrine Organs.* 4th ed. IARC Press; 2017; Amin MB, Edge SB, Greene FL, et al. *AJCC Cancer Staging Manual.* 8th ed. Springer International Publishing; 2017.

poorly differentiated, high-grade neuroendocrine carcinomas (NECs), typically with Ki-67 in excess of 50% to 70% (Table 76.2).[3] Well-differentiated G3 NETs tend to retain somatostatin receptor (SSTR) expression and grow more slowly with corresponding longer survival, whereas G3 NECs tend to show absent SSTR2 expression, unique genetic alterations, aggressive behavior, and poor survival.[3,37]

Staging in well-differentiated PNETs adheres to the American Joint Commission on Cancer (AJCC) 8th edition tumor-node-metastasis (TNM) system (see Table 76.2).[38] This staging system attempts to capture the extent of the primary tumor and, indirectly, resectability, as well as whether distant metastases exist. Distant metastases are present upon diagnosis in around 40% of patients in population-based studies, with some series reporting metastases in up to 60% of patients; at least 20% of patients have nodal metastases without distant metastases.[21,39] The 7th edition AJCC staging system followed the same definitions as exocrine pancreatic cancer. Although the exocrine pancreatic TNM designations still apply to poorly differentiated, high-grade NECs, they insufficiently discriminate outcomes in well-differentiated NETs, and the 8th edition modified the stage classifications in alignment with the system first proposed by the European Neuroendocrine Tumor Society (ENETS).[3,40,41] In the AJCC 8th edition, tumors <2 cm are T1, 2 to 4 cm are T2, T3 is >4 cm, and T4 tumors invade the celiac or superior mesenteric arteries or adjacent organs other than the duodenum or common bile duct. Nodal metastases indicate N1 disease. Stages I and II specify no nodal metastases and T1–T3 disease. Nodal metastases or T4 local extent define stage III, and distant metastases define stage IV. This system improves upon the 7th edition for survival discrimination by stage and has been validated in multiple populations.[42,43] A multicenter validation cohort of 1086 patients with PNET found median survival in stages I to IV of not reached, 115, 101, and 72 months, respectively.[43]

MOLECULAR FEATURES

Genetic alterations seen in sporadic PNETs differ from those present in adenocarcinoma. Mutations in *KRAS* and *TP53*, virtually ubiquitous in pancreatic adenocarcinoma, are absent in well-differentiated PNETs.[29,44] The much less common, high-grade, poorly differentiated pancreatic NECs typically show mutations in *TP53, RB1,* or both.[45] In well-differentiated tumors, mutations in *MEN1,* mTOR pathway genes (including *PTEN, TSC1, TSC2,* and *PIK3CA),* and *DAXX/ATRX* commonly occur and are seen in around 44%, 15%, and 43% of tumors, respectively.[29,39] Increased mTOR pathway signaling results from mutations in mTOR inhibitory genes and correlates with worse prognosis and more aggressive behavior.[23] Presence of unrestricted mTOR signaling in some PNETs forms the molecular rationale for treatment with mTOR inhibitors, such as everolimus.[46] In addition to these changes, clinically sporadic PNETs demonstrate a high prevalence of germline mutations in DNA repair genes, including *MUTYH, CHEK2,* and *BRCA2*, which were found in 11% of patients.[47]

Menin, encoded by *MEN1,* is a histone methyltransferase and cell cycle regulator responsible for the autosomal dominant MEN1 syndrome in those with germline mutations.[19] In MEN1 syndrome, germline inactivation of one copy of *MEN1* combined with somatic mutation of the other copy leads to the development of multiple pancreatic neuroendocrine microtumors.[23] In sporadic tumors, biallelic mutation or inactivation of *MEN1* similarly leads to dysregulation of the G1/S cell cycle transition and malignant transformation.[19]

The death domain associated protein *(DAXX)* and α-thalassemia/mental retardation syndrome X-linked *(ATRX)* genes function together in a transcription/chromatin remodeling complex that localizes to telomeres.[29] Mutually exclusive alterations in either *DAXX* or *ATRX* produce chromatin instability and a loss of normal telomere maintenance. Alternative lengthening of telomeres (ALT) occurs in the presence of compromised DAXX/ATRX activity, which is a telomerase-independent mechanism of tumor immortalization that can be detected by IHC.[23,29,48] With their role as tumor suppressors important to maintaining chromosomal stability, loss of *DAXX/ATRX* and the presence of the ALT phenotype in PNET cells lead to malignant transformation and confer a worse prognosis.[49,50] In PNETs, the presence of ALT predicts increased recurrence risk.[51] In an international cohort of 1322 NETs, DAXX/ATRX-negative or ALT-positive nonfunctional PNETs had 5-year recurrence-free survival rates of 40% and 42%, respectively, compared with 85% and 86%, respectively, for DAXX/ATRX-intact or ALT-negative tumors.[52] Current recommendations suggest routine molecular assessment for either *DAXX/ATRX* mutation or presence of the ALT phenotype in PNETs.[3]

Perhaps the most distinctive molecular feature of most well-differentiated PNETs is high expression of SSTRs on the cell surface. Increased SSTR expression occurs in around 90% of well-differentiated PNETs, and clinicians exploit this phenomenon for imaging and treatment.[46,53] High-grade tumors and insulinomas more commonly have low SSTR expression, with SSTR2-negative staining by IHC present in around 85% of high-grade PNETs/NECs and 40% of insulinomas.[45,46] In tumors with elevated SSTR expression, synthetic SSAs decrease hormone production and impair growth, improving progression-free survival (PFS).[54,55] SSAs conjugated to radioisotopes permit preferential accumulation of those isotopes in tumor cells, allowing for tumor-specific imaging (^{68}Ga or ^{64}Cu) or radiotherapy (^{90}Y or ^{177}Lu PRRT).[56,57]

CLINICAL FEATURES

The clinical features of functional PNETs differ from those of nonfunctional tumors. Functional tumors are defined by the presence of a clinical syndrome and elevated hormone levels. These present with symptoms related to the excess hormone being produced and may lead to their recognition at an earlier stage. Nonfunctional tumors are often silent until quite advanced, when large tumors or liver metastases give rise to symptoms that lead to workup. Increasingly, clinicians discover less advanced nonfunctional PNETs on imaging obtained for unrelated complaints. Functional NETs of the small bowel often produce large amounts of serotonin and, particularly when more advanced, give rise to classic “carcinoid syndrome” symptoms of serotonin excess, including flushing, diarrhea, carcinoid heart disease, and hemodynamic lability, in as many as one-third of patients.[58] In the pancreas, functional NETs much less commonly produce excess serotonin, and clinical carcinoid syndrome is exceedingly rare.[59] Instead, functional PNETs classically elaborate a single pancreatic hormone for which they are named. These pancreatic hormone-omas and the constellations of symptoms that define them are reviewed next. These clinical syndromes have captured great academic interest, but it should be noted that even the most common represent only a fraction of all PNETs, and most are vanishingly rare (Table 76.3).

Insulinoma

Insulinomas are the most common functional PNET, with an incidence of 1 to 4 per million per year, and were the first described.[60] Insulinomas can autonomously produce large quantities of insulin, leading to potentially life-threatening hypoglycemia.[61] In 1924, shortly after Frederick Banting and Charles Best identified insulin and demonstrated its use in correcting hyperglycemia in juvenile diabetes in 1921–22,[62] the American surgeon Seale Harris suggested that hypoglycemia in five patients might result from excessive endogenous insulin secretion. William Mayo reported a patient in 1926 with severe hypoglycemia found to have a widely metastatic pancreatic tumor on exploration. On autopsy, injection of a preparation of this patient’s liver metastases lowered blood glucose in rabbits, marking the first report of metastatic insulinoma. The first cure after resection of a localized insulinoma by Canadian surgeon Roscoe Graham was reported in 1929, and soon after, Whipple and Frantz described the insulinoma triad of hypoglycemic symptoms, low blood glucose, and symptomatic relief with restoration of normoglycemia.[32]

Suspicion of insulinoma usually follows episodes of symptomatic hypoglycemia during exercise or fasting. Biochemical diagnosis requires laboratory evidence of hypoglycemia with inappropriately high insulin or proinsulin during a 72-hour period of fasting, with concurrent C-peptide testing to exclude surreptitious insulin administration.[63,64] Some patients with hypoglycemia have tumors that produce proinsulin rather than insulin, but these cases are rare.[65] Standard contrast-enhanced CT or MRI imaging localizes most insulinomas, which are hypervascular and may enhance on

TABLE 76.3 **Functional Pancreatic Neuroendocrine Tumors**

TUMOR	CELL OF ORIGIN	INCIDENCE (CASES PER MILLION PER YEAR)	CLINICAL FEATURES	COMMENTS	REFERENCES
Insulinoma	β cell	1–4	Whipple triad: Hypoglycemic symptoms (sweating, tremors, blurred vision, confusion, seizures) during fasting, hypoglycemia, correction with restoration of normoglycemia	Tend to present early, usually localized, low-grade, can be cured by resection. May be multiple in MEN1.	32,60,62,64
Gastrinoma	G cell	1–1.5	Severe reflux, diarrhea, recurrent ulceration of stomach, duodenum, upper jejunum	Most located in duodenum, 25% in pancreas. 20%–30% of gastrinomas associated with MEN1. More often metastatic to nodes or liver.	75,150
Glucagonoma	α cell	0.1	Necrolytic migratory erythema, glossitis, cheilitis, hyperglycemia, weight loss, thromboembolism	Symptomatic patients have severe protein wasting, may require TPN before intervention.	32,76–78,151
VIPoma		0.05–0.2	Profuse watery diarrhea, hypokalemia, achlorhydria, hypercalcemia, flushing	Neurotransmitter stimulating enteric smooth muscle contraction, pancreas secretion.	33,82
Somatostatinoma	D cell	0.01–0.05	Diabetes, diarrhea/steatorrhea, cholelithiasis		85,152
PPoma	Y cell	Case reports	No clinical syndrome	Tend to be large at diagnosis.	90

arterial and venous sequences.[63] Many lesions are isoenhancing on CT, and MRI has greater sensitivity at 70% to 90%, making high-field MRI with contrast and diffusion-weighted sequences a good option for localization.[66,67] Even highly symptomatic insulinomas may be small, making some tumors difficult to find. Endoscopic ultrasound (EUS) reports high success rates in finding small tumors and allows simultaneous biopsy.[63] For very small tumors failing less invasive methods, localization through selective arterial stimulation with venous sampling facilitates resection.[67] This method combines selective angiography to illuminate the tumor's hypervascular features with selective arterial calcium administration, which stimulates insulin release. Angiography and measurement of insulin in the hepatic veins after selective calcium injection can isolate the tumor location to the head, body, or tail of the pancreas with >94% accuracy.[63] Insulinomas frequently overexpress glucagon-like peptide-1 (GLP-1R), and radioisotope-labeled agents targeting this receptor show potential for imaging small tumors.[61]

Insulinomas remain localized to the pancreas, solitary, low grade, and <2 cm in more than 90% of cases, but some can show higher grade, larger size, and metastases. Patients with MEN1 often have multiple tumors. Small, localized insulinomas have excellent survival approaching 100% with resection, whereas those >2 cm or with metastases have 10-year survival below 30%.[64] For metastatic insulinomas, diazoxide improves hypoglycemia in around 50% of patients, but side effects are common. Diazoxide should be stopped at least a week before surgery because of risk of intraoperative hypotension.[68] For patients failing diazoxide, SSAs may help, but can show less benefit than in other hormonal excess syndromes due to lower rates of SSTR overexpression. In some cases, hypoglycemia may actually worsen with SSAs due to glucagon inhibition.[26] Other interventions used for PNETs, including everolimus, chemotherapy, liver-directed therapies, and PRRT, can also be employed.

Gastrinoma

In 1955 Zollinger and Ellison described two young females with recurrent perforated upper GI ulcers who were found to have very high acid secretion and non–β-cell pancreatic tumors. They suggested that these patients represented a syndrome where a new form of pancreatic tumor secreted an unidentified hormone (they wrongly suspected glucagon), causing excessive acid secretion.[69] Gastrin, which is synthesized by G cells located mainly in the gastric antrum, had been identified in 1905, but that gastrinoma was the cause of Zollinger-Ellison syndrome (ZES) only became clear in 1967 when gastrin was isolated from a PNET.[1] Gastrinomas tend to originate within the "gastrinoma triangle," defined by the base of the cystic duct, the junction of the second and third portion of the duodenum, and the neck of the pancreas.[70] Most arise in the duodenum, with around 25% located within the pancreas. As in Zollinger and Ellison's first patient, whose father died of a peptic ulcer and sister of an insulinoma, 20% to 30% of patients with a gastrinoma have MEN1.[32,69]

Gastrinomas remain difficult to diagnose. Symptoms such as reflux and diarrhea are widespread and nonspecific, and improvement with proton pump inhibitors (PPIs) can mask true hypergastrinemia. Even with documented hypergastrinemia, whether this results from pharmacologic acid suppression or gastrinoma may remain uncertain. Gastrin above 10 times the upper limit of normal confirms ZES. In other cases, the gold standard for biochemical diagnosis requires documenting elevated gastrin at a confirmed gastric pH of <2 and a dramatic increase during a secretin stimulation test. Such testing, however, is rarely performed due in part to its complexity but also because of the danger of discontinuing PPIs and provoking gastrin secretion in a patient suspected of the disease, which can precipitate GI perforation. More commonly, a mass seen in the pancreas or duodenum on cross-sectional imaging and/or EUS in a suspicious clinical context produces the diagnosis. Gastrinomas within the pancreas are usually visualized by a combination of MRI and ^{68}Ga-DOTA-PET; however, sensitivity is lower for small duodenal tumors.[32] Some patients with negative localization studies other than nodal disease will have normal gastrin levels after resection and are thought to have their primary tumors originate within lymph nodes.[71]

Gastrinomas behave more aggressively than insulinomas, with liver metastases present in 30% of patients at diagnosis and nodal metastases in 60%.[32,72] Controlling acid secretion with high-dose PPIs decreases complications caused by ulceration and perforation. Surgical resection improves hypergastrinemia and may improve survival, but metastatic recurrences are common, with about half of patients whose gastrin levels initially normalize developing recurrent hypergastrinemia at 10 years.[73–75] Treatment for metastatic disease follows the multimodal strategies employed for nonfunctional PNETs.

Glucagonoma

Glucagon was first isolated in 1923, and in 1942 the dermatologist William Becker reported on the clinical features of malignant glucagonoma in a patient with hyperglycemia, necrolytic migratory erythema of the legs, which spread to the trunk, glossitis, and weight loss who was found to have a metastatic pancreatic tumor on autopsy.[32] In 1966, glucagon was first isolated from a metastatic pancreatic tumor in a patient with glucagonoma symptoms.[76] Glucagonomas are extremely rare, with an incidence of around 1 in 10 million.[77] Around half are metastatic at presentation, and only ~60% of confirmed glucagonomas produce both hyperglycemic symptoms and the characteristic dermatologic findings.[78] Biochemical diagnosis is by measurement of fasting glucagon greater than 500 pg/mL.[33] Persistently high glucagon leads to severe malnutrition and protein wasting. Amino acid infusion or parenteral nutrition improves dermatologic symptoms, and in very symptomatic patients may be necessary before surgical intervention.[79,80] Ten-year survival approaches 100% in resected patients without metastases and was reported at 52% in 87 resected metastatic glucagonomas.[78]

Vasoactive Intestinal Peptidoma

Vasoactive intestinal peptide (VIP) is a neurotransmitter found in the central nervous system and multiple organs throughout the body, including neuroendocrine pancreatic cells.[33] Verner and Morrison first reported the VIPoma syndrome of watery diarrhea, hypokalemia, and achlorhydria (WDHA syndrome) in two patients found to have PNETs in 1958.[81] After isolation of VIP and development of a blood assay, elevated VIP was documented in a patient with a PNET in 1973.[82] Patients with VIPoma syndrome may have 6 to 8 L of diarrhea per day, leading to severe electrolyte abnormalities and potentially fatal arrhythmias.[81,83] Facial flushing and hypercalcemia can be seen, and VIPomas may develop in the setting of MEN1.[82] Most VIPomas develop in the pancreas; however, as VIP-producing cells exist throughout the body, extrapancreatic VIPomas may also occur. Pancreatic VIPomas are found most commonly (70%) in the body and tail of the gland.[82] Markedly elevated fasting VIP (>200 pg/mL) in the setting of profuse diarrhea provides a biochemical diagnosis of VIPoma, whereas slightly elevated VIP can occur in heart failure or renal disease.[33] VIPomas may metastasize to the liver (21%), with 5-year survival of >90% for localized versus 60% for metastatic tumors.[84] Surgical and medical therapies follow those for other PNETs.

Somatostatinoma

Somatostatinomas arise in the pancreas, duodenum, or jejunum and produce high levels of somatostatin (SST), which inhibits multiple gut hormones, including insulin, glucagon, gastrin, secretin, cholecystokinin, and others.[85] First described in 1977, the somatostatinoma syndrome includes diabetes, cholelithiasis, and often diarrhea/steatorrhea caused by reduced pancreatic endocrine and exocrine function.[86–88] Only a few hundred reports exist in the literature, with an incidence estimated at 1 in 40 million.[85] Some PNETs without clinical features of somatostatinoma stain for SST on IHC. These should be considered nonfunctional, SST-positive PNETs, with somatostatinomas being defined by high serum SST and clinical symptoms of hypersomatostatinemia.[33]

In addition to these better-described, but still rare, functional PNETs, other extraordinarily rare PNETs have been reported to produce adrenocorticotropic hormone (ACTH) (and ectopic Cushing syndrome), parathyroid hormone–related peptide, calcitonin, and growth hormone–releasing hormones.[33] These should be resected when possible.

Pancreatic Polypeptidoma

Pancreatic polypeptide (PP) is a 36–amino acid hormone secreted by PP (also known as *upsilon*) cells mainly in the right side of the pancreas and was first isolated in 1968 as a contaminant during purification of chicken insulin.[89,90] Pancreatic polypeptidomas (PPomas) are extremely rare, with fewer than 100 reported in the literature, and they secrete high levels of PP, which normally functions in response to food to inhibit pancreatic secretion and stimulate gastric secretion.[91] PPomas do not produce a clinical syndrome; they are often recognized because of their large size, producing mass-effect symptoms in the head of the pancreas, or because of metastatic disease.[90]

Nonfunctional Pancreatic Neuroendocrine Tumors

Nonfunctional tumors do not cause syndromes associated with hormonal excess and account for up to 90% of PNETs.[8] As they produce no characteristic symptoms early in their course, nonfunctional tumors more often present with more advanced stage, and more than half have metastasized to nodes or liver at the time of diagnosis.[12] Some have detectable hormonal production on IHC or tumor marker investigations, but in the absence of clinical symptoms, these are termed nonfunctional.[26] Presenting symptoms include mass-effect symptoms of obstructive jaundice or duodenal obstruction for tumors in the head or uncinate or early satiety with larger tumors of the body and tail. The increasing incidence of PNETs is likely due in part to the frequency of abdominal imaging being performed for a variety of abdominal symptoms,[21] where these tumors may be picked up with or without corresponding liver metastases.

DIAGNOSIS

The diagnosis of a PNET may result from workup for a clinical syndrome in the case of functional tumors, but whether functional or not, confirmation will require the finding of a mass within the pancreas. This is commonly achieved by a CT scan, often done for another abdominal symptom. Characteristically PNETs enhance on the arterial phase and will look whiter than the normal pancreas because of the higher density of blood vessels, especially in functional PNETs. Nonfunctional PNETs can less commonly appear as hypodense. It is important to have both arterial and venous phases,[92] as when only a standard venous phase CT is done, the lesion may or may not be seen, as the differential enhancement from the normal pancreas will have passed (Fig. 76.1). A biphasic CT can pick up lesions as small as 5 mm in size and should not miss many lesions >10 mm in size (Fig. 76.2). A CT scan gives excellent anatomic detail of the relationship of the tumor to the important vascular structures, such as the superior mesenteric and splenic veins, as well as the superior mesenteric artery, celiac axis, and splenic arteries. These are important determinants to resectability and can be viewed in axial, coronal, and sagittal planes to aid in operative planning. CT scans also can detect enlarged regional nodes, peritoneal disease, and liver metastases.

The other principal anatomic imaging modality is MRI. PNETs should look hypodense on T1 images and generally show enhancement on T2 sequences (Fig. 76.3).[93] Magnetic resonance cholangiopancreatography images can also be obtained, which nicely delineate the pancreatic and biliary ductal systems. An MRI scan with gadoxetic acid (Eovist) is the preferred scan for imaging the extent and distribution of liver metastases and will often demonstrate more and smaller lesions than revealed by CT. Another advantage to MRI over CT scans for diagnosis and surveillance is the lack of ionizing radiation and lower nephrotoxicity of contrast agents. Many surgeons may prefer CT because of fewer sequences, less susceptibility to respiratory artifact, greater coverage of the abdomen and pelvis, and better discrimination of nodal and peritoneal metastases. However, high-quality MRI offers the highest sensitivity for liver metastases and can show vascular and anatomic relationships in great detail.

Functional PET imaging represents another imaging category that can be extremely useful in working up patients with PNET. Whereas most NETs will not be detected by standard 18 F-fluorodeoxyglucose–positron emission tomography (^{18}FDG/PET), NET functional studies, abbreviated as DOTA-PET, take advantage of the high expression of SSTRs on these tumors. Modified octreotide peptides are chelated to radioactive isotopes to bind to these receptors and can be imaged by PET, which has completely replaced the earlier generation of scans (^{111}In-pentetreotide scintigraphy).[56] DOTA-PET imaging agents in the United States, include ^{68}Ga-DOTATATE, ^{68}Ga-DOTATOC, and ^{64}Cu-DOTATATE. These PET scans can be fused with CT or MRI images captured at the same time, with or without IV contrast (Fig. 76.4). These scans can confirm that suspicious lesions are actually NETs, and uptake can be seen in primary tumors, nodes, and metastases. They are therefore helpful for determining the extent of disease and scan the whole body for potential metastases. They may reveal bone metastases not seen on CT scans, mediastinal nodes, supraclavicular nodes, and other areas of potentially resectable disease that the surgeon might not have otherwise recognized. In interpreting these images, high uptake is expected in the spleen, kidneys, bladder, ureters, adrenals, and pituitary as well as some background uptake within the liver and bowel. False-positive uptake is frequently seen in the uncinate process of the pancreas and sometimes in the tail of the pancreas, which can be further confused by the presence of accessory spleens. It is therefore important to not rely exclusively on a DOTA-PET scan for surgical decision-making for primary PNETs. Instead, other anatomic imaging can confirm that an abnormality exists in the

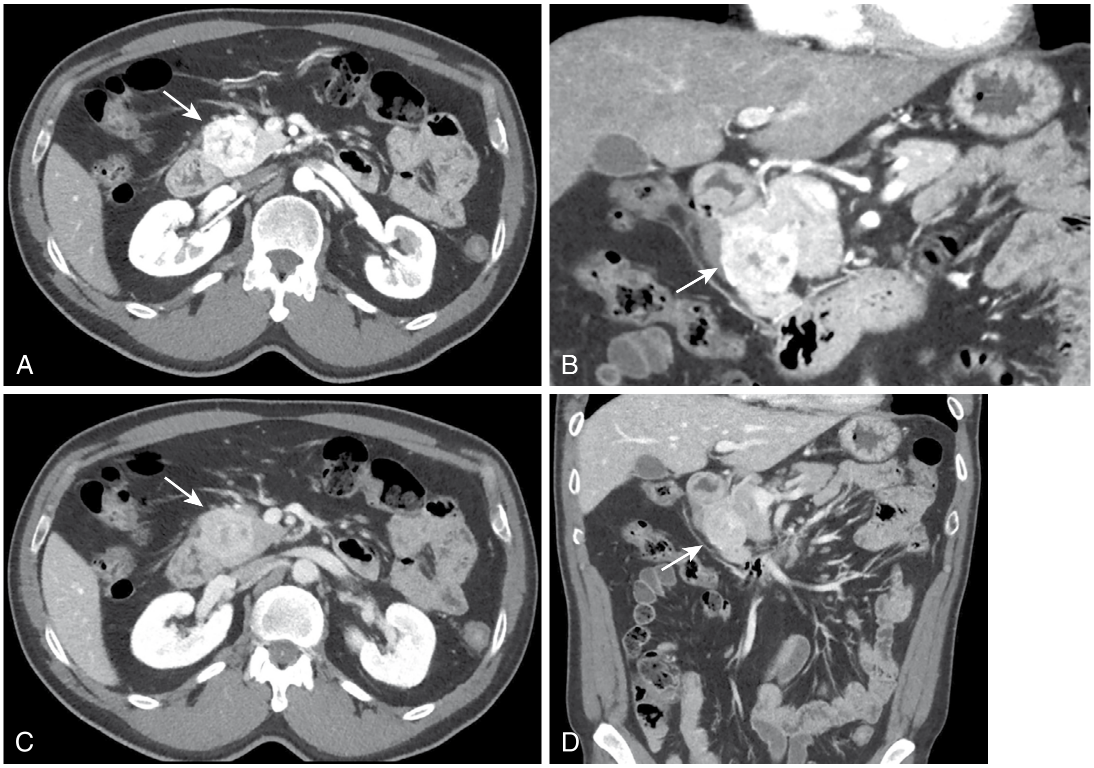

FIGURE 76.1 Comparison of arterial versus venous phase computed tomography for nonfunctional PNET. Transaxial (A) and coronal slices (B) in the arterial phase demonstrate a 4.1 × 3.5 cm enhancing mass in the pancreatic head *(white arrow)*. Transaxial (C) and coronal images (D) on the venous phase still show some enhancement, but significantly less than the arterial phase. *PNET,* Pancreatic neuroendocrine tumor.

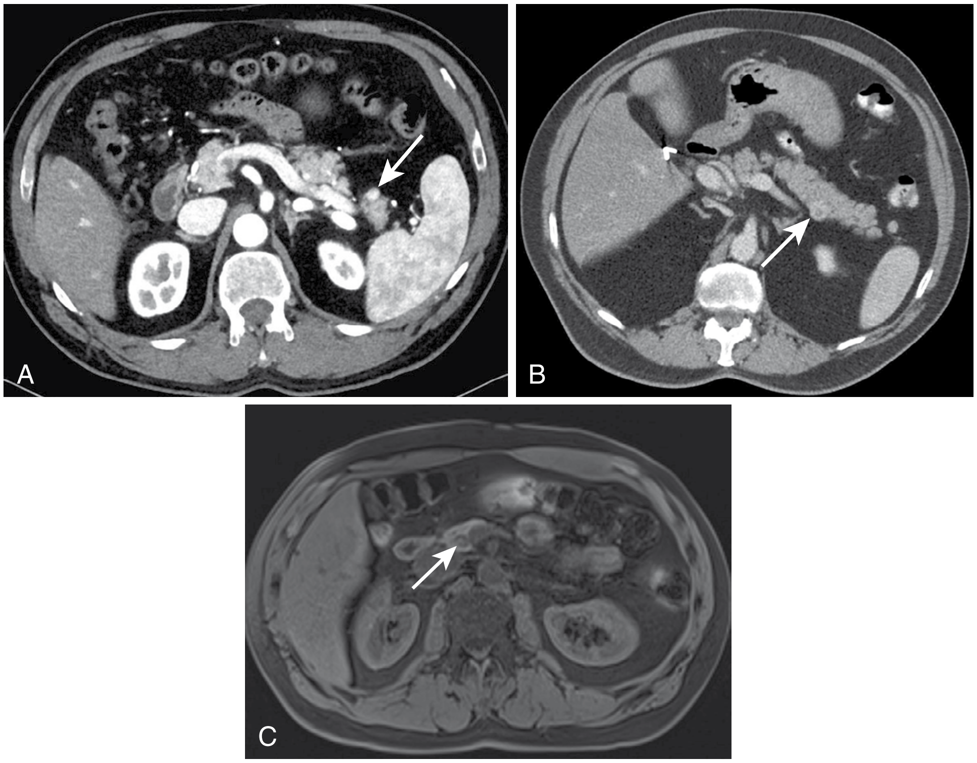

FIGURE 76.2 Transaxial arterial phase computed tomography (CT) showing an incidentally found, 8-mm, arterially enhancing lesion in the pancreatic tail (A), likely a PNET *(arrow)*. Enhancing 10-mm lesion incidentally found in the pancreatic body on transaxial CT (B), and 10-mm lesion of the pancreatic head on T1-weighted magnetic resonance image in a patient with symptomatic hypoglycemia (C). *PNET,* pancreatic neuroendocrine tumor.

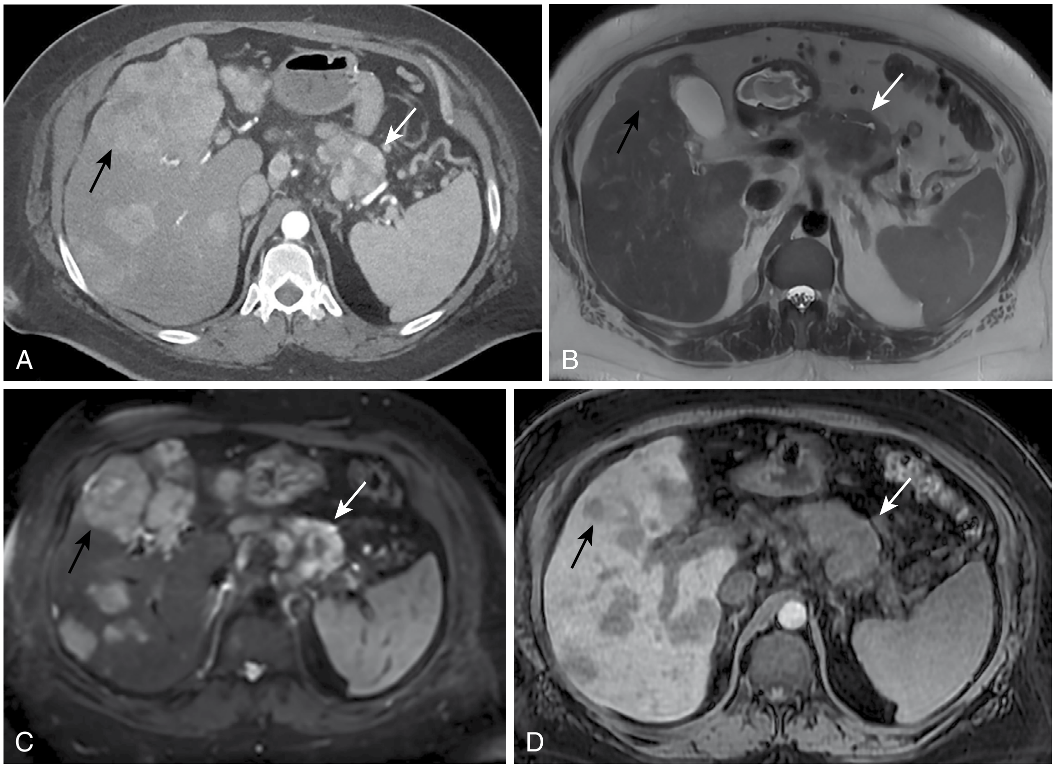

FIGURE 76.3 Transaxial arterial phase computed tomography (CT) (A) in a patient with a large pancreatic tail neuroendocrine tumor *(white arrows)* with nodal and liver metastases *(black arrow),* as compared with transaxial magnetic resonance imaging (MRI) with T2 (B), diffusion (C), and T1 sequences (D). Note the distinct information conveyed on different MRI sequences, with diffusion images showing the best delineation of liver lesions.

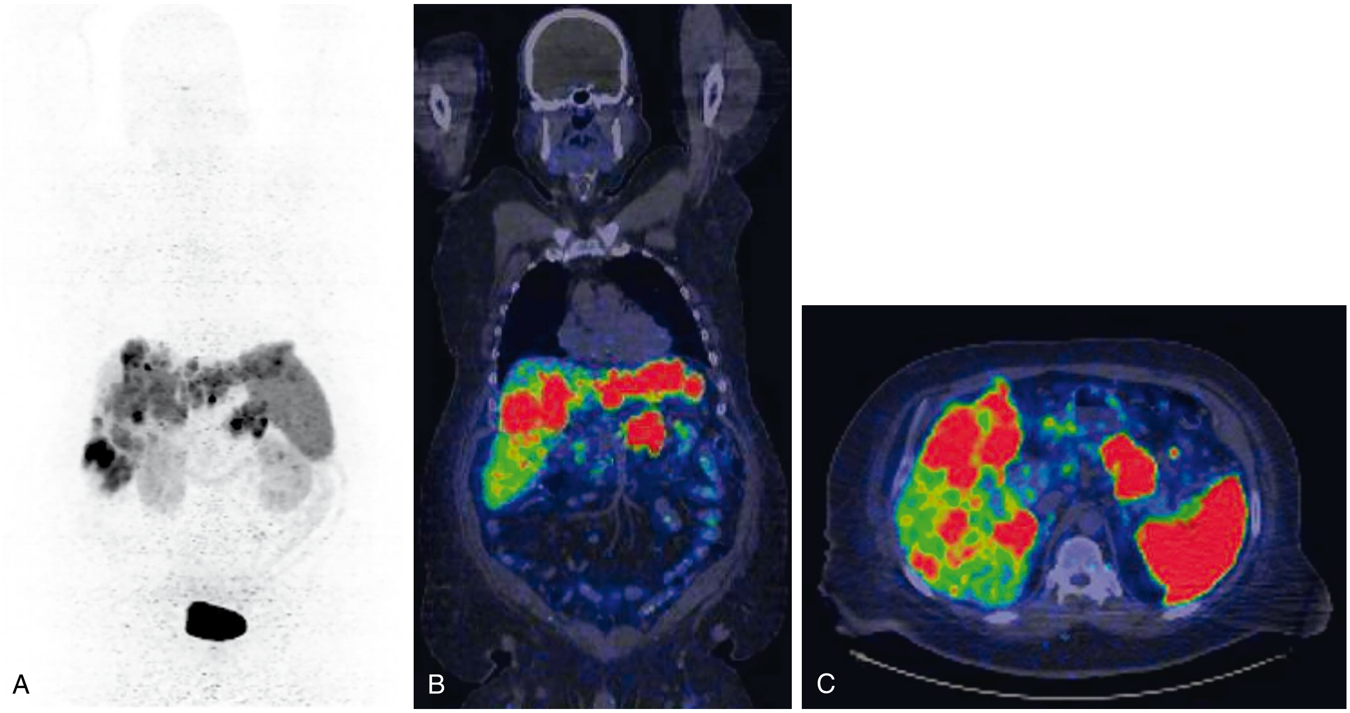

FIGURE 76.4 ^{64}Cu-DOTATATE scan of the same patient in Fig. 76.3. The maximum intensity projection image (A) gives an overview of the whole body, which shows many liver metastases, a large primary tumor, and enlarged nodes. The coronal fused computed tomography image (B) gives more anatomic information, as does the transaxial view (C). On this scan, areas of high somatostatin uptake are shown in *red.*

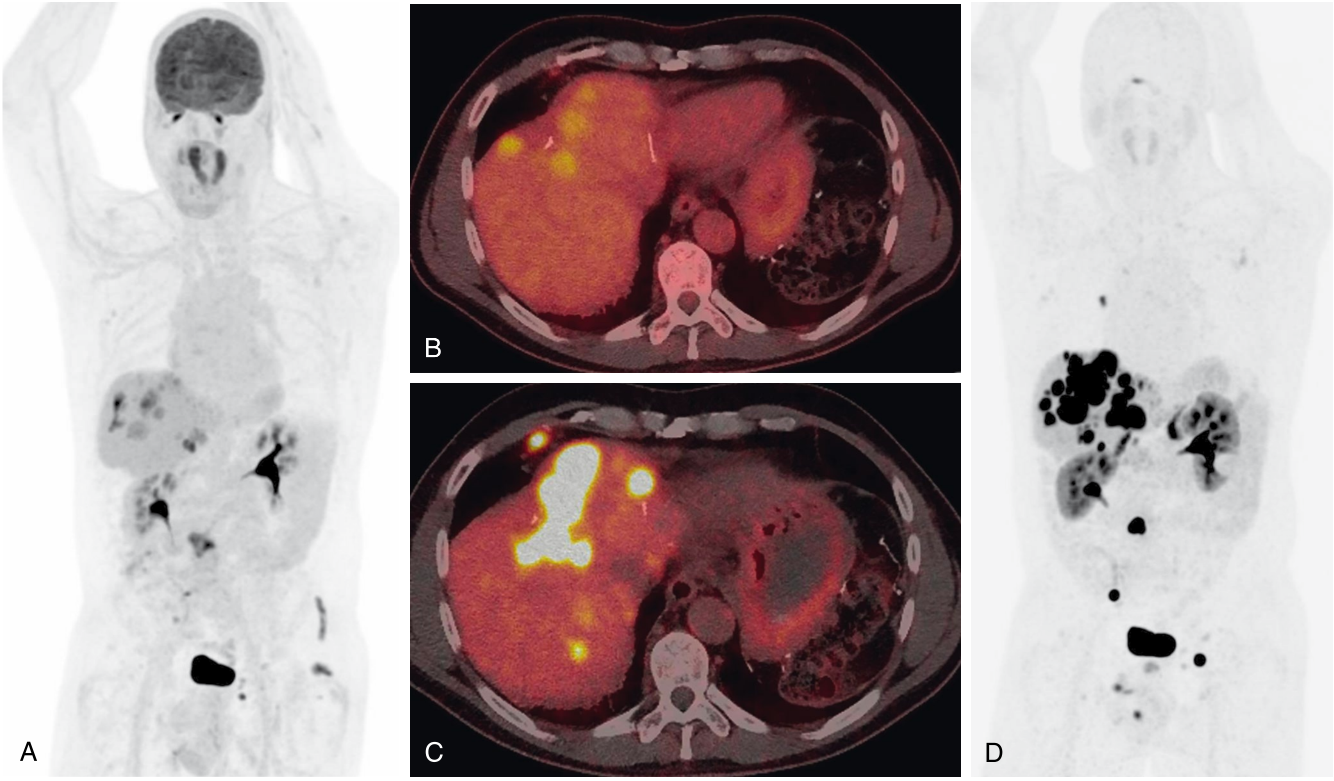

FIGURE 76.5 Comparison of ^{18}FDG/PET and ^{68}Ga-DOTATOC PET/CT scans taken 2 weeks apart in a patient with progressive PNET liver metastases. Surgical specimens from 7 months earlier revealed well-differentiated liver tumors with Ki-67 of 18%, 42%, and 67%. The ^{18}FDG/PET MIP image (A) reveals a few areas of uptake in the liver also seen on the transaxial fused image (B). The ^{68}Ga-DOTATOC transaxial fused CT image (C) and the MIP reveal higher levels of uptake in the liver as well as in L4, left ischium, and right iliac bone. *^{18}FDG/PET,* 18 F-fluorodeoxyglucose–positron emission tomography; *MIP,* maximum intensity projection; *PET/CT,* positron emission tomography–computed tomography; *PNET,* pancreatic neuroendocrine tumor.

region suggested by the PET scan and to rule out that it might be a false positive. An important limitation of DOTA-PET scans is that higher-grade tumors often fail to express SSTRs and may not be detected. These less common higher-grade tumors represent a clinical situation where standard ^{18}FDG/PET scans may show disease, and some patients with high-grade tumors may require both types of PET scans for workup (Fig. 76.5).

When a mass is suspected, EUS provides another means for high-resolution imaging evaluation and allows for diagnostic biopsy (Fig. 76.6). This requires sedation and is more invasive, but it can confirm the presence of a pancreatic lesion and show its relationship to adjacent organs and structures. One can also perform fine-needle aspiration (FNA) or core biopsy to confirm the histology, and other pathologic features can be determined that might affect the decision to operate, like Ki-67,[94] the presence of DAXX/ATRX, and/or ALT status.[3,95]

Biochemical testing for PNETs includes testing for hormone elevation indicative of a functional tumor and for other, more generic NET markers.[96] For insulinoma, fasting glucose, c-peptide, a sulfonylurea screen, and insulin are useful. For gastrinoma, a serum gastrin is checked, but this may be falsely elevated by PPI use. VIP, glucagon, and, less commonly, SST round out the commonly evaluated functional hormones. Rare tumors may make ACTH or parathyroid hormone (PTH)–related protein, which would be suggested by Cushing syndrome or hypercalcemia. Patients with hyperparathyroidism should be screened for MEN1. PP has been used for monitoring patients with PNET, but can be highly variable. Chromogranin A (CGA) is a general NET marker that can be useful in following patients with PNET, especially those with metastases. Pancreastatin, a subfragment of CGA, is also useful in many patients and is less affected by PPI use than CGA.[97] Serotonin is elevated in a fraction of patients with PNET. These hormone levels should be checked preoperatively, and levels that are found to be elevated may be helpful for determining tumor recurrence or progression in follow-up.

Analysis of pathology specimens should conform to the current WHO standards and includes differentiation status and Ki-67 and/or mitoses in order to be able to accurately assign grade.[98] Other useful pathologic determinants on tumor biopsies are the NET IHC markers CDX2, Islet1, PAX6, or PAX8. These transcription factors can help to confirm whether NET liver metastases or pancreatic tumors originate from the small bowel (CDX2 positive) or pancreas (Islet1, PAX6, or PAX8 positive).[99] Other important features in higher-grade tumors are the status of p53 and Rb, as these are lost more commonly in NECs. The status of the DAXX and ATRX proteins and ALT are also useful for helping to determine prognosis.[3,100] For patients where there is suspicion of MEN1, VHL, NF, or TSC, germline genetic testing should be performed to understand whether these patients are at risk for other tumors.[96]

SURGICAL MANAGEMENT

Surgical resection is the preferred treatment for PNETs, but decision-making can be complex. Most functional tumors should

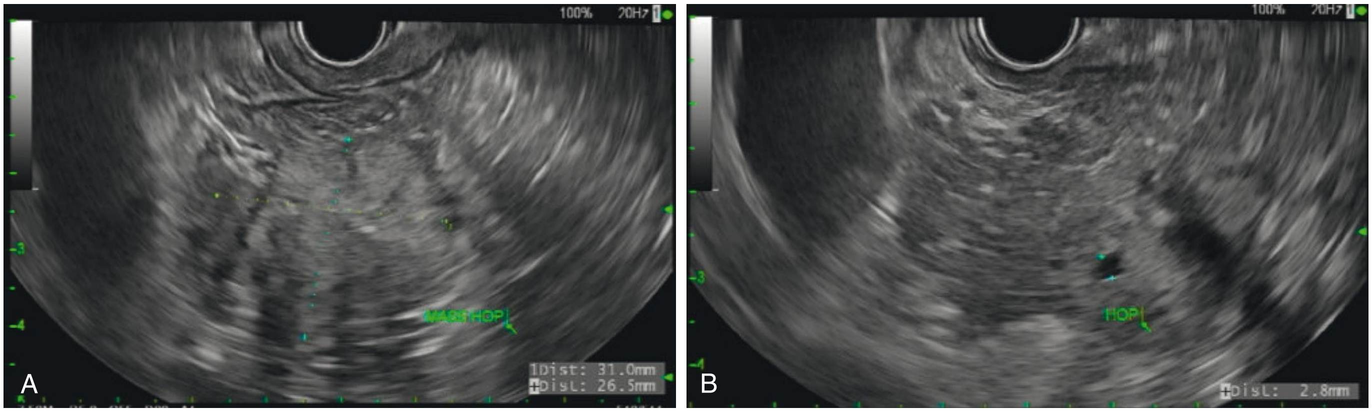

FIGURE 76.6 EUS from same patient shown in Fig. 76.1, demonstrating a 3.1 × 2.65 cm mass in the head of the pancreas (A) and a nondilated pancreatic duct 2.8 mm (B). Fine-needle aspiration revealed a well-differentiated NET with Ki-67 of 0.32%, with 70% of cells staining positive for SSTR type 2. *EUS,* Endoscopic ultrasound; *NET,* neuroendocrine tumor; *SSTR,* somatostatin receptor.

be resected regardless of size, because of the hormonal symptoms and complications associated with them. However, the majority of tumors are nonfunctional, and the decision to resect depends on the size of the tumor and extent of spread. In general, the risk of nodal or distant metastases in PNETs <1 cm is quite low, and these can generally be observed. With the increasing use of CT and MRI for a variety of conditions, small, incidentally discovered PNETs are common. Smaller, low-grade, nonfunctional tumors usually remain stable in size without metastases for long periods and can be observed. Tumors >2 cm, with higher Ki-67, or that show growth have an increased risk of nodal and distant metastases and should generally be resected in patients with reasonable performance status.[11] More controversial is the appropriate treatment of PNETs 1 to 2 cm in size, which again may remain small, but do have a low-intermediate risk of metastasis. The ASPEN trial in Europe is prospectively comparing results of resection versus observation of patients with these size tumors.[101] The decision to resect can be further influenced by the age of the patient (younger patients will need very long follow-up), their performance status, the location in the pancreas (tumors in the head requiring pancreaticoduodenectomy [PD] with higher risk of complications), and the grade of the tumor. Some have also suggested using FNA to identify tumors with DAXX/ATRX loss and ALT positivity, which suggest higher metastatic risk.[95]

If surgery is indicated, the choice of procedure depends primarily on the tumor's anatomic location. Perhaps the simplest procedure is enucleation, which is just an excision with narrow margins from within the pancreatic parenchyma (Fig. 76.7). This is best suited to benign lesions like insulinomas but can also be performed in lesions with malignant potential if the tumor is on the edge of the pancreas and at least 3 mm away from the main pancreatic duct. Enucleation can help to preserve pancreatic endocrine and exocrine function by removing minimal normal pancreatic tissue, but at the cost of increased risk of pancreatic fistula. When larger tumors are to be enucleated, regional nodal dissection should also be performed where possible.[11] Pancreatic parenchymal preservation takes on special importance in patients with genetic syndromes such as MEN1 or VHL, where multiple small, low-grade tumors will develop over the patient's lifetime.[31]

If the tumor is in the tail or distal body, then distal pancreatectomy (DP) is preferred. Important considerations here are whether to remove the spleen or not and whether it can be performed laparoscopically or should be done open. One of the major determinants again is the size of the tumor and local extent. Larger tumors tend to invade or occlude the splenic vein, leading to varices, and these are also more likely to have nodal and distant metastases. As such, an open procedure would be indicated in order to achieve the goals of primary tumor resection, regional nodal dissection, and liver cytoreduction, if necessary (Fig. 76.8). Some of these larger tumors will require partial gastrectomy or colectomy. For smaller tumors confined to the pancreas, laparoscopic DP has been shown to have similar complication rates as open procedures and with quicker recovery (Fig. 76.9).[102] Some prefer to use a 7- to 8-cm incision and a hand port for improved tactile feedback, to facilitate dissection, and for removal of the specimen with the spleen, if required. Splenectomy may not be necessary in all cases if the pancreas can be dissected off the splenic vessels. One may even transect the splenic artery and vein proximally and distally and keep the spleen if the short gastric vessels can be preserved, as popularized by Warshaw (see Fig. 76.9D).[103]

Smaller tumors in the body or neck of the pancreas can be treated by central pancreatectomy (CP), where the pancreas is divided proximal and distal to the primary tumor. This requires dissecting out the superior mesenteric vein (SMV) and splenic vein to keep these intact, then division of the pancreas over or to the left of the SMV, usually with a stapler, or, alternatively, it can be oversewn. The pancreas is then dissected off the splenic vein distally with preservation of the splenic artery to >1 cm beyond the tumor. The pancreas is divided sharply distally and bleeding vessels controlled. Regional nodal dissection to remove nodes along the splenic artery, celiac axis, and hepatic artery can also be carried out. A pancreaticojejunostomy to the distal pancreatic duct is next performed using a Roux-en-Y limb. For larger tumors in this location and in those with distal pancreatic atrophy, an extended DP may be preferable. Central resection will improve the potential for preserving endocrine and exocrine function, but with a higher risk of pancreatic leak.[104] Because these leaks are generally manageable with a surgical drain (with occasional need for an interventional radiology–placed drain), CP may be preferred for smaller lesions in this location.

If the tumor is in the head or uncinate process and not amenable to enucleation, then a PD (Whipple procedure) will be necessary (Fig. 76.10). This can be a classic Whipple procedure with associated gastric resection or pylorus-preserving. Laparoscopic and

robotic PD are being performed with increasing frequency with good results in some centers, but require advanced skills, and there is a significant learning curve.[105,106] As with all of these procedures, careful consideration should be given to the tumor's relationship to vascular structures, and if there is involvement of the SMV, consideration should be given to neoadjuvant capecitabine/temozolomide chemotherapy or PRRT to shrink the tumor. In general, PNETs are less likely to invade the SMV than pancreatic adenocarcinoma, and they can frequently be carefully dissected off the vein or hepatic artery. Occasionally, vein resection may be needed, which should not preclude resection if reconstruction is possible because of the good prognosis for resected PNETs. Another important consideration is whether there are liver metastases that need to be addressed or not. Once a biliary-enteric

anastomosis is performed (as in a PD), gut bacteria have free access to the liver; therefore, liver resections and/or ablations will have a much higher rate of infection. If liver cytoreduction is needed, this should be performed first and then the PD staged several months later to reduce the risk of hepatic abscess.[11]

In patients with familial syndromes, specifically with MEN1, VHL, and, less frequently, TSC, there are additional considerations. These patients are born with germline mutations that affect every diploid cell in their body, and the potential for multifocal metachronous tumors is extremely high. Therefore, operative planning needs to take into account the likelihood of future tumors and later need for additional pancreatic operations. In MEN1, it is recommended to wait until the largest lesion is >2 cm in size before performing surgery, and the resection should incorporate all or most of the lesions present.[107] This can be very difficult, as there may be small tumors distributed throughout the gland. In such situations, leaving the smaller tumors (<5 mm) alone may be the best option, while enucleating and resecting the larger lesions. In VHL, the situation becomes even more complex because patients may also have extensive pancreatic cystic lesions in addition to NETs. For patients with VHL, it is reasonable to wait until the tumor is >3 cm in size before recommending resection.[11,108] Enucleation is preferred when possible, and concurrent lesions <1.5 cm may be left alone.[31] A new drug (belzutifan) may be useful in patients with VHL to shrink these tumors or reduce their growth, and drugs including sunitinib, pazopanib, sorafenib, and others may be helpful for medical therapy of advanced disease.[109] Before any operation in a patient with known VHL, testing plasma metanephrines/normetanephrines to rule out pheochromocytoma is essential. A comparison of PNETs resected in patients with TSC versus sporadic PNETs found no recurrence or metastasis in the TSC group, suggesting potentially better tumor biology and a more conservative approach.[110]

National databases report that about two-thirds of patients with PNET have liver metastases.[111] Management recommendations for well-differentiated PNET liver metastases differ sharply from those for more aggressive histologies, such as colorectal adenocarcinoma. In functional PNETs, cytoreduction can improve symptoms even if all of the tumor cannot be eliminated, whereas in nonfunctional tumors, cytoreduction may help to improve

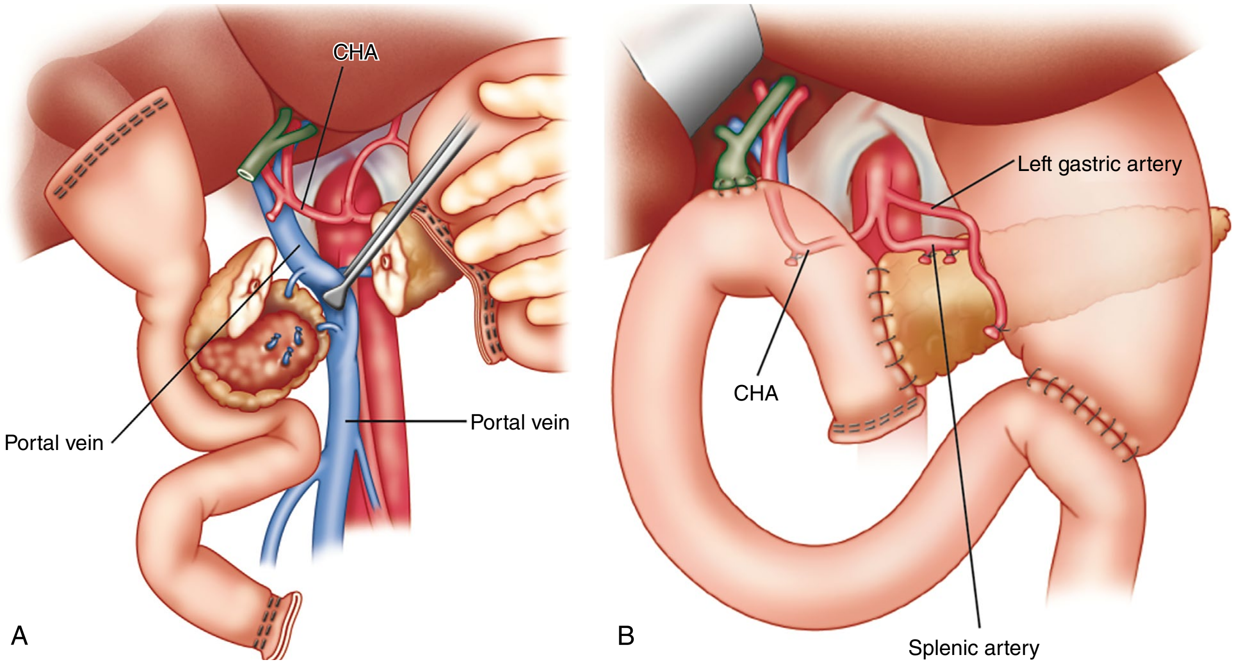

FIGURE 76.10 Division of pancreas, stomach, and jejunum for PNET in pancreatic head during pancreaticoduodenectomy (A). survival. Although controversy exists as to the extent of cytoreduction necessary to warrant an operation, if >70% to 90% of the tumor can be debulked from the liver, it is probably worth attempting in well-selected candidates.[112] As mentioned, if a patient requires a PD, then a staged hepatic cytoreduction procedure followed by a Whipple procedure later on would be the preferred approach.[11] If the patient is to have a DP, CP, or enucleation, cytoreduction can be performed at the same procedure. These cytoreductive procedures are rarely curative because micrometastases are often present, and recurrence rates are as high as 94% by 5 years.[113] Because of this and the frequent presence of bilobar and numerous tumors, parenchymal-sparing approaches are preferable.[11] This means resecting superficial lesions by wedge resections or enucleations, which have very low rates of local recurrence despite minimal margins because these tumors tend to push rather than invade the adjacent liver parenchyma. Deeper lesions may be treated with concurrent ablative techniques, such as microwave ablation, which can allow for treatment of many lesions when facilitated by intraoperative ultrasound. These procedures are well tolerated and result in minimal bleeding. However, great caution must be used with lesions sitting along major portal structures, as the heat generated can impair inflow or lead to bile duct strictures. For these lesions, irreversible electroporation, which may spare normal tissues better, is a reasonable ablative alternative.[114]

MEDICAL THERAPY FOR PANCREATIC NEUROENDOCRINE TUMORS

A characteristic shared by most NETs that can be exploited for diagnosis and therapy is a high density of SSTRs. These G protein–coupled receptors activate antisecretory and antiproliferative pathways upon ligand binding. Their ligand is SST, a peptide of 14 or 28 amino acids made in the brain, hypothalamus, GI tract, and pancreas. SST is an inhibitory hormone that reduces secretion of insulin, glucagon, gastrin, other GI hormones, pancreatic enzymes, and neuropeptides. Native SST has a short half-life of 2 to 3 minutes, but the synthetic 8–amino acid analog octreotide also has excellent binding affinity and improved half-life of 90 to 120 minutes. Octreotide was initially used to treat patients with acromegaly, but soon found utility in managing the debilitating diarrhea and flushing in patients with carcinoid syndrome.[115] A depot form of octreotide (octreotide-LAR) was formulated in 1997 that allowed for sustained levels in the body for up to 28 days. This made treatment of a variety of conditions more practical with once-monthly rather than three-times-daily subcutaneous injections.[116]

SSAs can help patients with functional PNETs through their antisecretory effects. They have proven useful in managing hypoglycemia in patients with insulinoma, can reduce gastric acid levels in those with gastrinoma, reduce diarrhea in patients with glucagonoma, and decrease levels of VIP from VIPomas.[117] They also hold utility for those with nonfunctional tumors through their antiproliferative effects. The PROMID randomized trial showed improved PFS in patients with advanced midgut NETs treated with long-acting octreotide as compared with placebo (14.3 vs. 6 months).[54] This led to approval of SSAs for advanced midgut NETs and, by extrapolation, to PNETs as well. A similar randomized trial (CLARINET) using another long-acting SSA (lanreotide) in patients with GEP-NETs also showed improvements in PFS versus placebo (not reached vs. 18 months); the median PFS in the PNET patient subgroup was 29.7 months.[55] For patients with metastatic PNETs, treatment with SSAs after surgical management is often the preferred first line of therapy to halt progression. Side effects are usually mild with these agents and may include loose stools, abdominal cramping, flatulence, pancreatic insufficiency, and thyroid and insulin suppression. Their use can also promote gallstone formation, so cholecystectomy should be considering when operating on advanced PNETs.

Several agents targeting specific biologic pathways reduce PNET progression. The mTOR inhibitor everolimus improves PFS in patients with advanced PNET. In the RADIANT-3 trial, patients with advanced PNETs were randomized to everolimus versus placebo, and PFS times were 11.3 and 4.6 months, respectively.[118] About 41% of patients treated had serious adverse advents, such as abdominal pain, vomiting, fevers, and pneumonia. Less severe common adverse reactions are stomatitis, rash, diarrhea, and edema. Sunitinib is a multikinase inhibitor of the vascular endothelial growth factor (VEGF) pathway that has also shown efficacy in PNETs. A randomized trial of patients with advanced or metastatic PNETs who were not surgical candidates revealed a PFS of 11.1 months for sunitinib versus 5.5 months for placebo, with an objective response rate of 9.3%.[119] Diarrhea, nausea, vomiting, fatigue, neutropenia, and hypertension were common. In 2021, the HIF-2α inhibitor belzutifan was approved by the FDA for VHL-associated tumors, including PNETs. In a trial of patients with VHL and renal cell carcinoma, 12 patients who also had PNETs showed an objective response rate of 77%.[109] The drug commonly causes decreased hemoglobin/anemia, hypoxia, and fatigue, among other side effects. Whether these impressive response rates in PNETs will apply to patients without VHL remains to be seen, and phase II clinical trials that include advanced, sporadic PNETs and pheochromocytoma/paraganglioma are underway (NCT04924075).

For patients with advanced, well-differentiated PNETs, the oral chemotherapy combination of capecitabine and temozolomide (Cap/Tem) has shown response rates of 40% and improved PFS versus temozolomide alone (22.7 vs. 14.4 months).[120] Overall survival (OS) was similar in both groups (58.7 vs. 53.8 months). This combination can be extremely useful in the neoadjuvant setting for shrinking both primary and metastatic lesions before attempted resection and cytoreduction as well as for treating patients with progressive disease (Fig. 76.11). The combination is generally well tolerated by patients, with the most common side effects including anemia, thrombocytopenia, granulocytopenia, fatigue, vomiting, and nausea. In patients who progress after previous Cap/Tem treatment, the fluorouracil, leucovorin, oxaliplatin (FOLFOX) regimen shows activity, with response rates of 45% in this population.[121] Patients with poorly differentiated, high-grade PNETs are commonly treated with cisplatin or carboplatin and etoposide, with response rates of 30%, but survival in these aggressive carcinomas remains poor at a median of about 1 year.[122]

Peptide radioreceptor therapy is another treatment for patients with advanced PNETs. This is the intravenous administration of a radioisotope chelated to an SSA, which can bind specifically to tumor cells expressing SSTRs. It is internalized into the tumor cell, allowing the radioactive molecule to carry out DNA damage. Early versions used^{111} indium and^{90} yttrium[123] and more recently most have used^{177} lutetium.[124] Although used for decades in Europe based on phase II trials, PRRT was not approved in the United States until 2018. This followed results of the NETTER-1 trial, where patients with advanced midgut NETs were randomized to four cycles of^{177} Lu-DOTATATE plus octreotide LAR 30 mg every 4 weeks versus Sandostatin LAR 60 mg every 4 weeks. The early end point of 20-month PFS was 65.2% for the PRRT versus 10.8% for the control group ($p < 0.001$).[125] Based on this study and several from Europe, the FDA approved PRRT for patients with advanced PNET and GI NET with SST-avid tumors. PRRT is generally used after surgical cytoreduction when there has been progression on SSAs, but can also be used in unresectable or borderline resectable PNETs in a neoadjuvant setting.[126] This therapy is well tolerated, but 2% may develop myelodysplastic syndrome or leukemia in long-term follow-up.[127]

There are a variety of options for the medical treatment of functional tumors. Excess gastric acid secretion can be managed by PPIs and further enhanced with SSAs.[128] For insulinoma, diazoxide can be very helpful in raising blood sugars, as well as frequent meals.[129] For unresectable VIPomas and glucagonomas, SSAs may be useful to help control the hypersecretory state.[130]

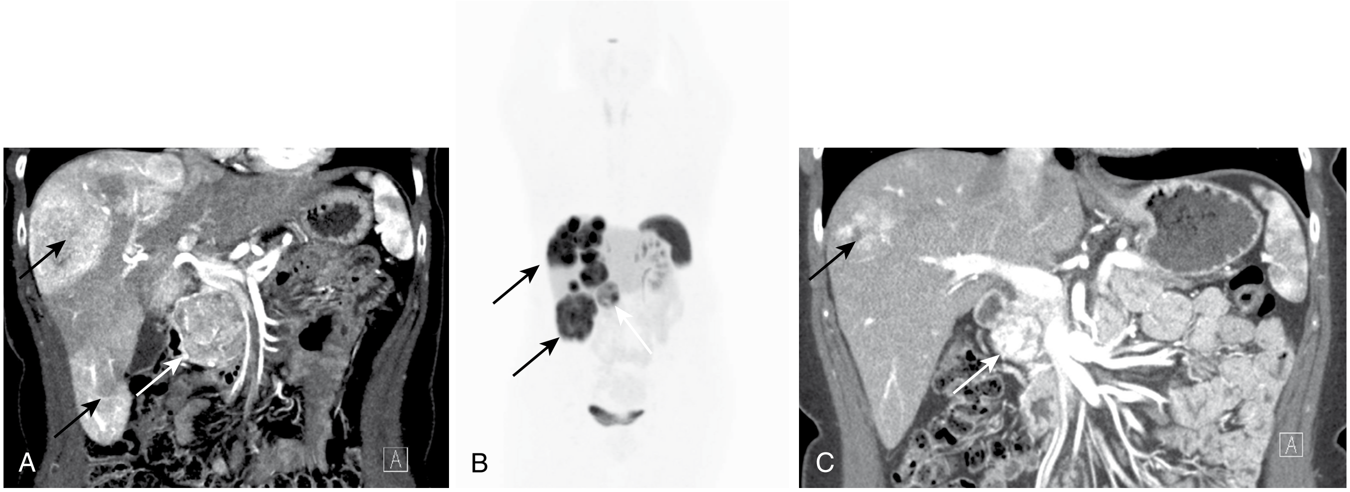

FIGURE 76.11 Coronal CT of patient with PNET in head of the pancreas (A). The *white arrow* shows the primary tumor, and *black arrows* show large liver metastases. ^{68}Ga-DOTATOC MIP image (B) showing liver metastases *(black arrows)* and primary tumor *(white arrow)*. Coronal CT (C) after 12 months of neoadjuvant capecitabine and temozolomide chemotherapy, showing substantial decrease in the size of liver *(black arrow)* and primary tumors *(white arrow)*. *MIP,* Maximum intensity projection; *PNET,* pancreatic neuroendocrine tumor.

OUTCOMES

Pancreatic surgery in general is well recognized for its relatively high morbidity and mortality rates.[131] Mortality for PD ranges from 2% to 16%, which correlates with hospital volume,[132] and should be <5% in high-volume centers.[133,134] Major complications such as pancreaticobiliary leaks, delayed gastric emptying, hemorrhage, abscess, aspiration, and pulmonary embolism are also common. Most pancreatic surgery outcome studies reflect primarily patients with adenocarcinoma, and complication rates may differ for operations performed for PNETs. The morbidity and morbidity also depend on whether PD, DP, CP, or enucleation is performed. A systematic review of pancreatectomies performed for PNETs revealed in-hospital mortality rates of 6%, 4%, 4%, and 3% for these respective procedures.[135]

The pancreas is often less fibrotic and more commonly has a nondilated duct in patients with PNETs, which increases the risk of pancreatic fistula.[136] One review found a pancreatic fistula rate was 45% for enucleation, 58% for CP, 14% for DP, and 14% for PD.[135] Delayed gastric emptying is more common after PD and CP (18% and 16%, respectively), as is postoperative hemorrhage (7% and 4%, respectively).[135] Rates of reintervention and readmission are higher with PD and enucleation of head lesions (46% and 49%) and lower for DP and enucleation of tail lesions (19% and 24%).[137]

The most common long-term complications related to pancreatic resections are exocrine and endocrine insufficiency. The risk of these sequelae generally correlate with how much pancreas is removed, favoring procedures such as enucleation and CP. In a Dutch study of patients with PNET, exocrine insufficiency was seen in 55% having PD, 8% with DP, and 5% after enucleation.[137] One US center found the incidence to be 36% in those having PD or DP.[138] Exocrine insufficiency is also influenced by whether gastric antrum and duodenum are present, receipt of chemotherapy and/or radiation, the patency of the pancreaticoenteric anastomosis, and whether the patient is receiving SSAs. Symptoms may include steatorrhea, flatulence, bloating, abdominal cramping, nausea, weight loss, and oily/yellow stools. Fecal elastase levels in a random stool sample may be helpful in making the diagnosis but are less reliable than in chronic pancreatitis. Pancreatic enzyme replacement therapy with 50 to 75,000 units of lipase per meal and 25 to 50,000 units for snacks are recommended starting doses in patients with exocrine insufficiency, and some would start these perioperatively.[139] Standard encapsulated porcine pancreatic enzymes can be expensive, and for some, chewable over-the-counter papaya extract can be a reasonable alternative.

Endocrine insufficiency is also common after pancreatic resections, and in a series of over 1700 patients having PD or DP, endocrine insufficiency (defined by the need for pharmacologic intervention) occurred in 20% of patients. Risk factors included higher BMI, smoking, family or personal history of diabetes, and DP over PD, possibly because of a higher density of islet cells in the tail of the pancreas. Patients should be followed by fasting glucose and hemoglobin A1c levels and educated on the symptoms (polyuria, polydipsia, blurred vision) and long-term complications of hyperglycemia (stroke, coronary artery, renal, and peripheral vascular disease).[138] Glycemic control must be monitored postoperatively and in follow-up, and patients may need to be on oral hypoglycemics or insulin if hemoglobin A1c remains elevated.

In patients with functional tumors, resection of the primary tumor may allow for the disappearance of symptoms. However, if residual nodal or metastatic disease is present, symptoms and elevated hormone levels may persist. The highest chance for cure would be in patients with insulinoma where the tumors are generally small but are detected early because of the pronounced symptoms of hypoglycemia. Other functional tumors are less likely to be localized, and cure will be more difficult. In a high-volume-center series of resected PNETs, one-quarter were functional tumors (17% insulinoma, 3% glucagonoma, 3% gastrinoma, 2% other), and the hazard ratio (HR) for PFS was significantly reduced as compared with nonfunctional tumors (HR 0.272, $p = 0.012$ by multivariate analysis).[140]

In the Surveillance, Epidemiology, and End Results program (SEER) database, 8944 PNETs were recorded between 2000 and 2016. The median OS of the entire group was 68 months, increasing from 46 months between 2000 and 2008 to 85 months between 2009 and 2016. Five-year OS was excellent for localized tumors, at 83.2%, diminishing to 67.4% in those with regional nodal disease and 28.1% with metastatic disease. In patients with metastatic grade 1 and 2 tumors who had surgery, median OS was 84 months versus 18 months in those not having surgery.[21] In the Verona database of 587 patients with resected PNET, where only 13% had stage IV disease and the median tumor size was 2.0 cm, the median disease-specific survival (DSS) was 269 months for all patients. Vascular invasion, higher tumor grade, and liver metastases were independent risk factors for decreased survival.[140]

Some controversy exists over the risks associated with smaller PNETs (<2 cm). In a study of the National Cancer Database (NCDB), Sugawara et al. compared survival of patients with localized, nonfunctional PNETs ≤1 cm and 1.1 to 2.0 cm. Over 80% of each group had resection, and resection was associated with improved survival for the 1.1- to 2.0-cm group (HR 0.58, $p < 0.001$) but not for the <1-cm group. The median OS was not reached in the <1-cm group, and incidence of nodal metastases was 6.1% versus a median OS of 186 months and 10% nodal metastases in the 1.1- to 2.0-cm group. They concluded that select patients with 1.1- to 2.0-cm tumors may benefit from resection (<65 years old, no comorbidities, and distal pancreas location).[141] A European study from 16 centers reviewed their experience with 210 resected PNETs <2 cm. Of these, 10.6% had positive nodes and 5.9% developed metastases (liver, nodes, lung), with 1 local recurrence. The 5-year OS was 96.2%, with 5-year DSS of 100% in the <10-mm group and 87.3% in the 11- to 20-mm group. Higher tumor grade (grade 2 to 3), biliary or pancreatic dilatation, and tumor size 11 to 20 mm were independent risk factors for recurrence.[142] The morbidity and mortality of pancreatic surgery need to be carefully factored versus the risk of decreased survival from the tumor. This risk in PNETs <10 mm appears negligible, and for tumors 11 to 20 mm, resection might be reserved for good-risk patients with grade 2 to 3 tumors and/or ductal dilatation.

In MEN1, the problem of multifocality can make the choice of operation challenging.[25] Furthermore, up to three-quarters of patients will develop new tumors in the remnant pancreas, sometimes requiring completion pancreatectomy.[143] In a study of 603 patients with MEN1 with duodenopancreatic tumors with median follow-up of 6.9 years, 67 patients died. Distant metastases developed in 36 patients; 46 of the deaths were considered NET related, 8 were non-NET cancer related, and 13 were the result of other medical conditions.[144] An older study following 57 patients with MEN1 with PNETs and ZES found that liver metastases occurred in 23% of patients and 14% had an aggressive growth pattern. Three deaths were attributed to ZES, and

8 patients died of other causes.[145] In a Dutch study of 69 patients with MEN1 with PNETs having surgery, 10 patients developed liver metastases, and all of these patients had primary tumors >3 cm; no liver metastases were seen in patients with tumors <2 cm.[146]

In patients with VHL, PNETs <3 cm also rarely metastasize; therefore, because of their multifocality and the complexity of coexistent cystic lesions, it has generally been recommended to delay resection until they reach >3 cm in size.[31,147] Recommendations from North American Tumor Society (NANETS) suggest that patients with PNETs >3 cm, a tumor doubling time of <500 days, or germline mutations in exon 3 of the *VHL* gene should be considered for surgical resection.[11]

SURVEILLANCE AND FOLLOW-UP

The European Society of Medical Oncology (ESMO) recommends that for follow-up of PNET patients that a CT or MRI be performed every 3 to 6 months for R0/R1 resected grade 1 or 2 GEP-NETs, decreasing to every 2 to 3 months for grade 3 NECs. In patients with advanced disease, the intervals should be the same, and surveillance should be lifelong, but intervals can be increased to 1 to 2 years as follow-up time increases.[148] Recent ENETS guidelines for nonfunctional PNETs resected with curative intent (including metastatic) suggest anatomic imaging (CT chest, abdomen, and pelvis or abdominal MRI) be performed at 3 to 6 months after surgery, then every 6 to 12 months for 5 years, then every 1 to 2 years until 10 years, and every 5 years thereafter. If liver metastases are being followed, this should be every 3 months, preferably by MRI. A DOTA-PET scan should be considered every 1 to 2 years to more fully evaluate for metastases, and chromogranin A levels may help assess tumor burden. If metastatic disease is not resected, then recommendations are similar, but the importance of using the same modality (preferably MRI with liver disease) is stressed so that response evaluation criteria for solid tumors (RECIST) criteria can accurately be used to determine whether changes in treatment are needed.[149]

CHAPTER 77

Neuroendocrine Neoplasms (Carcinoid Tumors)

Andrea Gillis, Sophie Dream, and Herbert Chen

OUTLINE

Introduction
Gastroenteropancreatic Neuroendocrine Tumors
  Gastric
  Small Intestine
  Appendix
  Colon and Rectal
  Pancreatic
Bronchopulmonary Neuroendocrine Tumors
Thymic Neuroendocrine Tumors
Multiple Endocrine Neoplasia Type 1 and Neuroendocrine Tumors
Metastatic Neuroendocrine Disease
Carcinoid Syndrome

INTRODUCTION

Neuroendocrine neoplasms or tumors (NETs), classically called *carcinoid tumors,* encompass tumors that derive from neuroendocrine cell origin. The term *carcinoid* implies benignity and, given the propensity for these tumors to metastasize, is now generally considered a misnomer. The median age of incidence is 60.5 years. They are rare, but increasing in incidence, with an annual age-adjusted incidence of 6.98 per 100,000 persons in 2012.[1] The majority of NETs occur throughout the gastrointestinal (GI) tract and are commonly classified based on their embryologic site of origin: foregut, midgut, or hindgut. As these tumors arise from neuroendocrine cells, they can occur in other locations throughout the body, including the lungs, thymus, and bronchi, but less commonly.

NETs of the GI tract are generally not associated with hormone hyperproduction but can cause carcinoid syndrome, especially in cases with metastasis. In contrast to these GI tract NETs, bronchopulmonary and thymic NETs can cause both carcinoid syndrome and Cushing syndrome.

GASTROENTEROPANCREATIC NEUROENDOCRINE TUMORS

The majority of neuroendocrine/carcinoid tumors are found within the GI tract (55%). Neuroendocrine tumors of the intestinal tract are categorized by grade and/or differentiation.[2] Well-differentiated NETs are distinguished from poorly differentiated neuroendocrine carcinomas. Grading is divided into three groups from low (G1), to intermediate (G2), to high grade (G3) based on mitotic rates, cell appearance, Ki-67 proliferation rates (determined by immunohistochemical staining for nuclear Ki-67 protein expression), and clinical features such as local or angioinvasion. Low-grade, well-differentiated NETs carry a favorable prognosis, with 5-year survival ranging to >98% with appropriate treatment. The majority of NETs are "nonfunctioning," meaning not secreting metabolically active substances such as gastrin, serotonin, insulin, and vasoactive intestinal peptides (VIPs). Additional classification relates to the tumor's cell of origin, which influences NET presentation, metastatic potential, and prognosis.

CT scans may be a useful diagnostic tool or may incidentally find these tumors. The use of multiphasic contrast-enhanced CT scan with a timed arterial and venous phase is crucial to identifying these lesions, which are hyperenhancing on arterial phase and isoenhancing on delayed phases. MRIs are particularly useful for identifying metastases such as within the liver. Because NETs tend to overexpress somatostatin receptors, functional imaging targeting somatostatin receptors are the most sensitive for diagnosing and staging neuroendocrine neoplasms. For example, somatostatin receptor–positron emission tomography (PET) scans (^{68}Ga-DOTATATE) are now the gold standard for reliably identifying these tumors. This test uses gadolinium, which binds to somatostatin receptors to allow for localization and staging.

Gastric

Gastric carcinoids or NETs comprise about 7% of all digestive NETS.[3–5] These tumors originate from the histamine-containing enterochromaffin-like (ECL) cells of the embryonic foregut. Of all gastric neoplasms, NETs are quite rare (about 1.8%), with an incidence of 0.5 per 100,000 persons.

Clinical and histologic features of gastric NETs can be divided into three subtypes (Table 77.1). Type I gastric NETs are the most common (70%–80%). These tend to present as multiple small, benign tumors. Their formation is associated with the loss of parietal cells and chronic atrophic gastritis leading to G-cell hyperplasia and hypergastrinemia from lack of inhibitory feedback.[6] ECL cells are then upregulated and become hyperplastic and then dysplastic tumors. When atrophic gastritis is associated with parietal cell or intrinsic factor antibodies, the patient is diagnosed with pernicious anemia.

Type II gastric NETs (5%) are associated with multiple endocrine neoplasia type 1 (MEN1) and Zollinger-Ellison syndrome (ZES). These tumors are driven by ectopic gastrin-producing

TABLE 77.1 **Common Characteristics of the Three Types of Gastric Neuroendocrine Tumors**

TYPE	PREVALENCE	MALIGNANT POTENTIAL	SIZE	LOCATION	GASTRIC PH	FASTING GASTRIN	ASSOCIATED SYNDROMES
Type I	70%–80%	Usually benign	Small (≤1 cm)	Fundus or body	High: pH >4–7	High	Pernicious anemia
Type II	5%	Malignant potential but usually indolent	Large (1–2 cm)	Fundus, body, antrum	Low: pH <2	High	MEN1, ZES
Type III	10%–15%	Highly malignant with metastatic potential	Large (>2 cm)	Fundus or antrum	Normal: pH <4	Normal	Atypical carcinoid syndrome

MEN1, Multiple endocrine neoplasia type 1; *ZES,* Zollinger-Ellison syndrome.

G cells (gastrinomas), usually in the duodenum or pancreas. Their development is thought to be induced by the presence of hypergastrinemia that is independent of normal inhibitory feedback. Clinically, these tumors tend to be larger than type I tumors with a higher risk of lymph node metastasis (5%–35%). The diagnosis of a type II gastric NET mandates screening for MEN1-associated tumors (pituitary and parathyroid; see later).

Type III gastric NETs (15%–25%) are also usually large (similar to type II) but are not associated with hypergastrinemia or any aberrant gastric physiology. Similar to gastric adenocarcinoma, these tumors are highly aggressive with a tendency to metastasize (usually to lymph nodes, followed by liver). Type III gastric NETs are associated with an impaired 5-year survival rate (25%–30%) compared with other gastric NETs (70%–99%). They are also associated with "atypical carcinoid syndrome" because of the possibility of overproduction of 5-hydroxytryptophan (5-HTP) (see "Carcinoid Syndrome" later) (see Table 77.1).

Diagnosis of gastric NETs is usually incidental given their indolent nature. They are likely to be discovered on routine endoscopy where a mass is found. Both mass and normal gastric tissue should be sampled in order to subtype these tumors by looking for the presence (or absence) of G-cell hyperplasia, atrophic gastritis, and/or ECL hyperplasia. Once diagnosed, as with all gastric tumors, endoscopic ultrasound (EUS) should be completed to assess for lymph node involvement and depth of invasion, as this will dictate treatment. CT or MRI may be used for evaluation of metastatic disease. Serum chromogranin A (CgA) is measured as a biomarker and prognostic factor for all neuroendocrine neoplasms.

The treatment for gastric NETs should consist of wide local excision.[7] Negative margins without any specified length cutoff ("no tumor on ink") is sufficient given the typical indolent nature of these tumors. The exact surgical approach depends on tumor size, level of invasion, and presence of high-risk features. Those type I and II gastric NETs without evidence of lymph node involvement and no greater than submucosal invasion can be treated endoscopically with snare polypectomy or endoscopic mucosal resection (EMR). All type III gastric NETs or large (>1 cm), high-risk type I and II gastric NETs should be managed aggressively with wedge or partial gastrectomy and lymph node dissection. Those patients with numerous gastric NETs not amenable to wedge resections may require a total gastrectomy. Those with type II gastric NETs must have the culprit gastrinoma resected as well, if possible.

Small Intestine

The small intestine and appendix are the most common sites for gastroenteropancreatic (GEP) NETs. Small intestinal NETs comprise about 30% of small intestinal neoplasms. The median age at presentation is in the seventh decade.

Duodenal NETs are extremely rare, usually small, and remain localized. Most are located in the first or second part of the duodenum, and about 20% are located in the periampullary region. All duodenal NETs should be removed if diagnosed before metastases given concern for obstruction. The approach to removal depends on size, location, and lymph node involvement. Endoscopic resection can be selected for submucosal, nonampullary tumors <10 mm.[8,9] Between 1 and 2 cm, endoscopic resection or surgical resection can be considered. Large (>2 cm) or ampullary duodenal NETs or those with lymph node involvement should be surgically removed, which may necessitate a pancreaticoduodenectomy based on proximity to the pancreatic duct.

Most small intestinal NETs are located in the last 2 feet of the terminal ileum. Ileal NETs may be aggressive, with 35% associated with metastases. Diagnosis of NETs, as with all small bowel tumors, is generally illusive. Video capsule endoscopy or balloon-assisted enteroscopy may be helpful in localizing small intestinal NETs. Unfortunately, small bowel NETs typically do not clinically manifest until they have reached a large, symptomatic size—on average 3.5 cm or once they have metastasized. The symptoms usually consist of a partial/intermittent small bowel obstruction caused by either intussusception or luminal obstruction. Additionally, a dense desmoplastic reaction as a result of the NET may occur, exacerbating a small bowel obstruction. In advanced stages, mesenteric and nodal involvement may obstruct venous drainage and lead to ischemia. Given the significant risk of multiple tumors (20%–30%) and metastasis, all small bowel NETs are recommended to undergo full staging before resection.

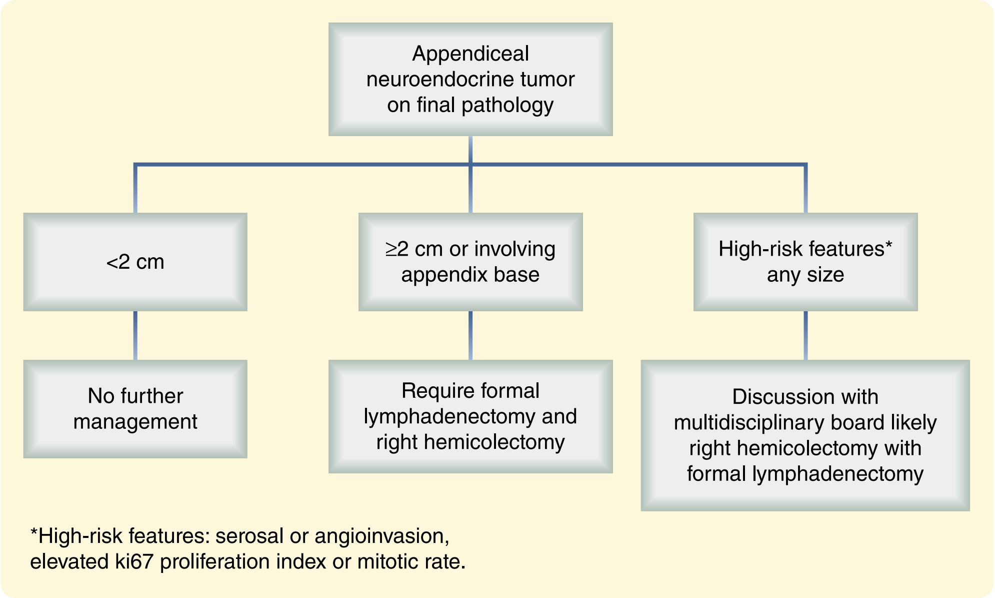
Surgical treatment is the standard of care. Minimally invasive (laparoscopic) or open surgical resection may be considered. Segmental resection along with locoregional lymphadenectomy is required to enhance disease-free survival. In widely metastatic disease, there are data that tumor debulking may increase long-term survival, but this is controversial.

Appendix

Appendiceal NETs are the most common neoplasm affecting the appendix (60%–80%).[10] Lymph node metastasis rates increase with tumor size, affecting 15% of appendix NETs <1 cm, 47% of those 1 to 2 cm, and 86% of those larger than 2 cm. The 10-year survival rate ranges from 91% to 100% based on these sizes, with larger sizes portending worse survival.

Appendix tumors tend to present earlier than intestinal NETs elsewhere because of obstruction of the appendiceal lumen causing appendicitis.[11,12] This leads to many appendix NETs being diagnosed incidentally on final pathology. Several series report the prevalence of incidental NETs in appendectomy specimens to be about 1% to 1.5%.

All symptomatic and asymptomatic appendiceal tumors are recommended to be resected if known preoperatively given their malignant potential. The size of the appendiceal tumor dictates the operative management via an algorithm based on National



Appendiceal neuroendocrine tumor on final pathology
<2 cm
≥2 cm or involving appendix base
High-risk features* any size
No further management
Require formal lymphadenectomy and right hemicolectomy
Discussion with multidisciplinary board likely right hemicolectomy with formal lymphadenectomy

*High-risk features: serosal or angioinvasion, elevated ki67 proliferation index or mitotic rate.

FIGURE 77.1 Management algorithm for appendiceal neuroendocrine tumors. (From Hoehn RS, Rieser CJ, Choudry MH, et al. Current management of appendiceal neoplasms. *Am Soc Clin Oncol Educ Book.* 2021;41:1-15.)

Comprehensive Cancer Network (NCCN) recommendations (Fig. 77.1).[13] Larger tumors and tumors with higher risk of recurrence (high Ki67, poorly differentiated) mandate more aggressive, wider resections than appendectomy alone, including right hemicolectomy. This allows for a tumor basin lymphadenectomy along the ileocolic vasculature for staging.

Colon and Rectal

Colorectal NETs comprise the "hindgut" NETs. Colon and rectal NETs are typically found on routine colonoscopy. On endoscopy, colorectal NETs appear as a small, yellowish, waxy-looking sessile or submucosal polyp. They rarely produce serotonin, limiting the usefulness of 24-hour urine 5′-hydroxyindoleacetic acid for diagnosis or monitoring but may secrete somatostatin. Less than half of colorectal NETs will manifest with symptoms, including bleeding or changes in bowel habits.

Colonic NETs make up 16% of all GI NETs.[14] They are rare, but tend to be aggressive, with 40% rated as high grade. The average tumor size is 5 cm, and over 65% have nodal or distal metastases. Colonic NETs carry the worst prognosis of all luminal GI NETs.[15] Across all stages, colonic NETs carry an average 5-year survival rate of 40% to 70%, with cecal tumors having the best prognosis.

Rectal NETs comprise 34% of all GI NETs and have an excellent prognosis, especially if <2 cm (5-year overall survival 76%–88%). If low grade and <2 cm in size, colorectal NETs can be resected endoscopically with polypectomy and do not require formal staging.[16] However, larger or high-risk colonic NETs require full staging and a formal segmental resection. Similarly, high-risk rectal NETs mandate a total mesorectal excision because of the need for lymph node staging.

Pancreatic

NETs of the pancreas (pNETs) are rare among NETs (9%); however, among all NETs, pNETs carry the worse overall 5-year survival (74%, all stages).[4,17] These tumors will be thoroughly discussed in a subsequent chapter of this volume.

BRONCHOPULMONARY NEUROENDOCRINE TUMORS

Bronchopulmonary NETs comprise a group of rare lung malignancies made up of carcinoid/NET, small cell lung carcinoma, large cell neuroendocrine carcinoma, and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia.[18,29] The age-adjusted incidence of lung NETs was 1.49 per 100,000 persons.[1] This section of the chapter will focus on bronchopulmonary NETs that arise from the enteroendocrine (also known as *argentaffin* or *Kulchitsky*) cells of the lung.

The majority of bronchopulmonary NETs develop spontaneously and occur in the fifth and sixth decades of life. They account for a minority of lung cancers, with typical and atypical NETs of the lung representing less than 2% of lung tumors. Cigarette smoking has been associated with an increased odds ratio of developing pulmonary NETs, but the mechanism is unclear.[19]

Bronchial NETs usually present as centrally located endobronchial lesions, but also may present as peripheral lung nodules. They may secret serotonin, adrenocorticotropic hormone (ACTH), somatostatin, and bradykinin. Patients with bronchopulmonary NETs may be asymptomatic; however, the majority of patients will present with symptoms including cough, wheezing, chest pain, hemoptysis, and/or bronchial obstruction. Bronchial obstruction can result in lung hyperinflation, atelectasis, and recurring pneumonia distal to the site of tumor obstruction. Typical bronchial NETs may also be associated with lung hypoplasia, which may be the result of a reactive neuroendocrine hyperplasia.[20]

Although rare (Table 77.2), bronchopulmonary NETS may present with a secretory tumor that may cause carcinoid syndrome (see later) or produce ACTH resulting in Cushing syndrome (see Table 77.2). Classic features of Cushing syndrome include hypertension, hyperglycemia, weight gain, fatigue, easy bruising, thinning skin, striae, and mood disturbances.

When suspecting hypercortisolism, patients should be screened with a 1-mg overnight dexamethasone suppression test, two or

TABLE 77.2 Rate of Symptoms With Bronchopulmonary Neuroendocrine/ Carcinoid Tumors

SYMPTOM	RATE OF OCCURRENCE
Cough	35%–91%
Dyspnea	46%
Chest pain	~40%
Hemoptysis	25%–50%
Recurrent lung infections	33%
Carcinoid syndrome	1%–5%
Cushing syndrome	2%–4%
Asymptomatic	~25%

From Ramirez RA, Beyer DT, Diebold AE, et al. Prognostic factors in typical and atypical pulmonary carcinoids. *Ochsner J*. 2017;17(4):335-340; Wang T, Zhou J, Zheng Q, et al. A competing risk model nomogram to predict the long-term prognosis of lung carcinoid. *Ann Surg Oncol*. 2023;30(9):5830-5839.

more midnight salivary cortisol tests, or a 24-hour urine cortisol test.[23] Next, if patients do have hypercortisolism, an elevated morning ACTH and high-dose dexamethasone testing failing to suppress can elucidate the etiology as ACTH dependent from a nonpituitary source.

Bronchopulmonary NETs are often found incidentally on imaging. The majority of these tumors affect the mainstem or lobar bronchus. Initial evaluation is performed with CT chest with contrast and multiphasic axial abdominal imaging. Centrally located tumors can be further assessed with bronchoscopy, where these tumors appear as pink and rounded with a lobulated surface; irregular margins are more likely in atypical carcinoids. Biopsy can be safely done using bronchoscopy to confirm neuroendocrine cells.[24]

The 2022 WHO classification categorizes bronchopulmonary and thymic NETs/carcinoid tumors as low-grade typical and intermediate-grade atypical tumors based on the characteristics noted in Table 77.3.[25] Typical NETs are more likely to be well differentiated and less aggressive, whereas atypical NETs are more likely to be peripherally located, tend to be more aggressive, and are more likely to metastasize to local and regional lymph nodes and to distant sites, including the liver, bones, and brain. Atypical NETs may harbor *p53, BCL2,* or *BAX* gene mutations. Characteristics that confer worse prognosis include atypical carcinoid syndrome, increased age, male sex, larger tumor size, higher Ki-67 index (>10%), lymph node involvement, or metastatic disease.[21,22,26] Atypical tumors, centrally located tumors, and larger tumors are associated with more advanced lymph node metastasis.[27]

The overall prognosis of bronchopulmonary NETs is favorable when compared with other lung malignancies, with the majority of lung NETs being typical tumors. The goal of treatment for bronchial NETs is surgical resection, achieving an R0 or complete resection. Typical bronchial carcinoids can be treated with wedge resection in cases of peripheral tumors that are smaller than 2 cm in size, without lymph node involvement, or in patients with poor functional status when an anatomic resection is prohibitive. Anatomic lobectomy or segmentectomy is considered the standard of care for larger tumors, including lymph node dissection or sampling. In cases of atypical carcinoids, radical lymph node dissection is suggested because of the higher incidence of lymph node involvement in these patients.[28–30]

TABLE 77.3 Features of Typical and Atypical Bronchopulmonary Neuroendocrine Tumors

	LOW-GRADE TYPICAL	INTERMEDIATE-GRADE ATYPICAL
Necrosis	Not present	Present
Mitosis	<2 mitoses per 2 mm^2	2–10 mitoses per 2 mm^2
Chromogranin A	Positive immunostaining	
Synaptophysin	Positive immunostaining	
CD56	Positive immunostaining	

Intraluminal typical bronchial NETs have the potential to be treated with initial endobronchial resection and regular follow-up if complete resection is achieved because of the favorable prognosis of these tumors.[31] Typical bronchial NETs have an excellent prognosis, with 5-year survival rates of about 90% and 10-year survival rates of >80%, even in the setting of identified lymph node metastasis.[32–36] Atypical bronchial carcinoids have 5-year survival rates of 22% to 100% and 10-year survival rates of about 42% to 67%, with nodal metastasis having a significant impact on survival.[21,33,35,36] In cases where patient factors make surgical resection impractical, radiation therapy can be used. In advanced disease, patients are treated with adjuvant chemotherapy with cisplatin or carboplatin and etoposide and radiotherapy.[30]

THYMIC NEUROENDOCRINE TUMORS

Thymic neuroendocrine (or carcinoid) tumors are rare and make up about 5% of anterior mediastinal tumors.[31] They have a strong male predominance and are associated with MEN1 syndrome. Thymic NETs generally present as a large mass and often are locally invasive or have distant metastasis on initial presentation. Although the majority of these tumors are nonsecretory, they can produce ACTH. They are histologically classified by differentiation as well differentiated (low-grade typical), moderately differentiated (intermediate-grade atypical), or poorly differentiated/anaplastic (high-grade large cell neuroendocrine carcinoma or small cell neuroendocrine carcinoma), similarly to bronchopulmonary NETs (see Table 77.3). Patients with thymic carcinoids often present asymptomatically with a mass found on imaging, but may also present with chest pain, cough, and dysphagia related to mass effect in the mediastinum.

Thymic NETs are often discovered incidentally on screening chest x-ray or for mediastinal symptoms. Thymic NETs initially can be evaluated with contrast-enhanced chest CT scan, which can help delineate the presence of local invasion, regional metastasis, and features that may be indicative of multiple thymic tumors. On imaging, these tumors are lobulated and may demonstrate areas of necrosis or hemorrhage.

Tissue biopsy may be needed to rule out other tumors that have similar appearance on imaging that can be medically treated, including germ cell tumors or lymphoma. In cases where the tumor cannot be completely excised with thymectomy, tissue diagnosis with CT-guided fine-needle aspiration or endoscopic or bronchoscopy biopsy should be used to obtain tissue diagnosis. Cases where these less invasive approaches do not yield adequate tissue may necessitate surgical biopsy with mediastinoscopy, video-assisted thoracoscopy, or anterior mediastinotomy.

Once a thymic NET is diagnosed on tissue biopsy, additional abdominal cross-sectional imaging and baseline somatostatin receptor imaging (PET–DOTATATE) is performed for staging, tumor localization, and to confirm the presence of somatostatin overexpression. The overall mortality rate for thymic NETs is high, with the 5-year survival rate ranging from 25% to 56%. Patients who are treated with surgical resection, who have smaller tumors, and who have lower stage disease have improved survival.[37,38]

Thymic NETs are treated with resection, with complete surgical resection (R0) being the treatment of choice, as it confers the best overall survival.[31] In cases where complete resection is not possible, local radiation therapy can control residual disease. The addition of adjuvant chemotherapy with cisplatin or carboplatin and etoposide is suggested for poorly differentiated neuroendocrine carcinomas even in the setting of complete resection.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1 AND NEUROENDOCRINE TUMORS

Bronchial and thymic NETs occur in up to 25% of patients with MEN1.[39,40] These tumors are more likely to occur in males with MEN1, with some reports showing a 10:1 male-to-female predominance. Smoking has also been shown to be a risk factor for the development of thymic NETs in patients with MEN1. Although thymic NETs present late in MEN1, they are the second most common cause of death in patients with this condition, accounting for up to 20% of MEN1-associated mortality.[41] In this patient population, bronchial NETs have a more indolent course than thymic NETs.

Initial screening in patients diagnosed with MEN1 for bronchopulmonary and thymic NETs is important given the malignant potential. Screening with chest x-ray or chest CT with contrast is recommended for males over the age of 25 with MEN1 for thymic NETs, with repeat screening every 1 to 3 years. Imaging protocols for screening and surveillance are controversial because many MEN1-associated bronchopulmonary NETs have low rates of growth and high overall survival.[42] Biochemical evaluation is appropriate if patients exhibit clinical manifestations of carcinoid or Cushing syndrome related to serotonin or ACTH secretion, respectively.

Patients with type II gastric NETs should be evaluated for MEN1 given this syndromic association. An evaluation for the associated disorders of the pituitary and parathyroid should be ruled out.

METASTATIC NEUROENDOCRINE DISEASE

Metastatic disease because of NETs is fairly common, with rates ranging from 12% to 74% at presentation.[43] The liver and lymph nodes are the most frequent sites of metastatic disease, followed by bone, adrenal glands, and brain. Overall NET prognosis is heavily influenced by metastasis. In the United States, localized NET median overall survival is >30 years, those with regionally metastatic disease have a median overall survival of 10.2 years, and those with distant metastatic disease have a median overall survival of 12 months.[1] At times, NETs may be initially diagnosed from a biopsy of a metastasis. The primary tumor site should be delineated, if possible, to guide treatment.

Ideal treatment of metastatic neuroendocrine disease is surgical resection.[43] However, the level of tumor burden may not be safe or amenable to complete resection. Treatment of unresectable metastatic NET should consist of symptom management and tumor burden control, if able. Debulking of disease may improve overall survival even if complete cure is not achievable, although this is controversial. Deciding on exact staging and sequencing of surgical resection is complex and should be made in conjunction with a multidisciplinary team.

Those with liver metastases may present with carcinoid syndrome (see later) or a variety of symptoms related to the hypersecretion of neuroendocrine hormones. These secretory syndromes should be managed for symptom relief. Specific hormonal hypersecretion can be targeted with, for example, proton pump inhibitors for gastrinomas, diet control and glucagon for insulinomas, and metyrapone/ketoconazole for ACTH hypersecretion.

Systemic therapy may be offered to shrink tumor burden and control all refractory hormonal hypersecretion.[44] This may include long-acting somatostatin analogues (SSAs) such as lanreotide or a serotonin inhibitor (telotristat). Kinase inhibitors (sunitinib), mammalian target of rapamycin (mTOR) inhibitors (everolimus), and radionuclide somatostatin therapy have also been used as second-line therapy. Cytotoxic agents are considered in patients with progressive disease who are not responsive to other treatments but have not been show to improve progression-free survival or disease-free survival.[30] CgA should be serially measured to monitor for response if downtrending.

At times, liver-directed therapies may be used in conjunction with or as a bridge to surgical resection. This may include ablative therapies such as radiofrequency or microwave ablation or regional therapies including transarterial chemoembolization, transarterial radioembolization, or peptide receptor radionuclide therapy (PRRT). These therapies may treat or shrink liver metastases, allowing a parenchymal-sparing liver resection that may be more tolerable to the patient. These therapies may also be used for palliative intent for symptom control.

Surgically, primary tumor resection and all metastatic disease caries the highest 5-year survival rates. In those with extensive metastatic disease that may be unresectable, debulking or cytoreduction may improve overall survival but is controversial.[45] Additional systemic treatment modalities may be offered in conjunction as well. For those patients with unresectable or medically unresponsive liver metastases, liver transplant may be considered an additional modality. Although rarely used in the United States, the 5-year survival rate for patients undergoing liver transplantation for unresectable NETs was 84% compared with 34% in those without surgical treatment.[46]

Overall survival in those with metastatic disease depends on the level of tumor burden, primary site tissue type, grade, and presence of high-risk features (Fig. 77.2).

CARCINOID SYNDROME

Carcinoid syndrome is uncommon and occurs in 10% to 30% of carcinoid cases.[47–49] It is driven by an overproduction of serotonin or tachykinin by neoplastic cells. In excess, this hormone can cause episodic skin flushing (reported in over 90%), edema (typically lower extremity), diarrhea (60%), and wheezing/dyspnea on exertion (15%). The typical flushing experienced by patients with carcinoid syndrome can range from violaceous, full body, episodic, or lasting multiple days. Diarrhea is extremely common and is often watery, postprandial, and explosive. Serotonin causes systemic vascular vasodilatation as well as fibrosis formation, which can increase risk of right-sided valvular dysfunction and heart failure.[49] The common cardiac manifestations are pulmonary stenosis (90%), tricuspid insufficiency (47%), and

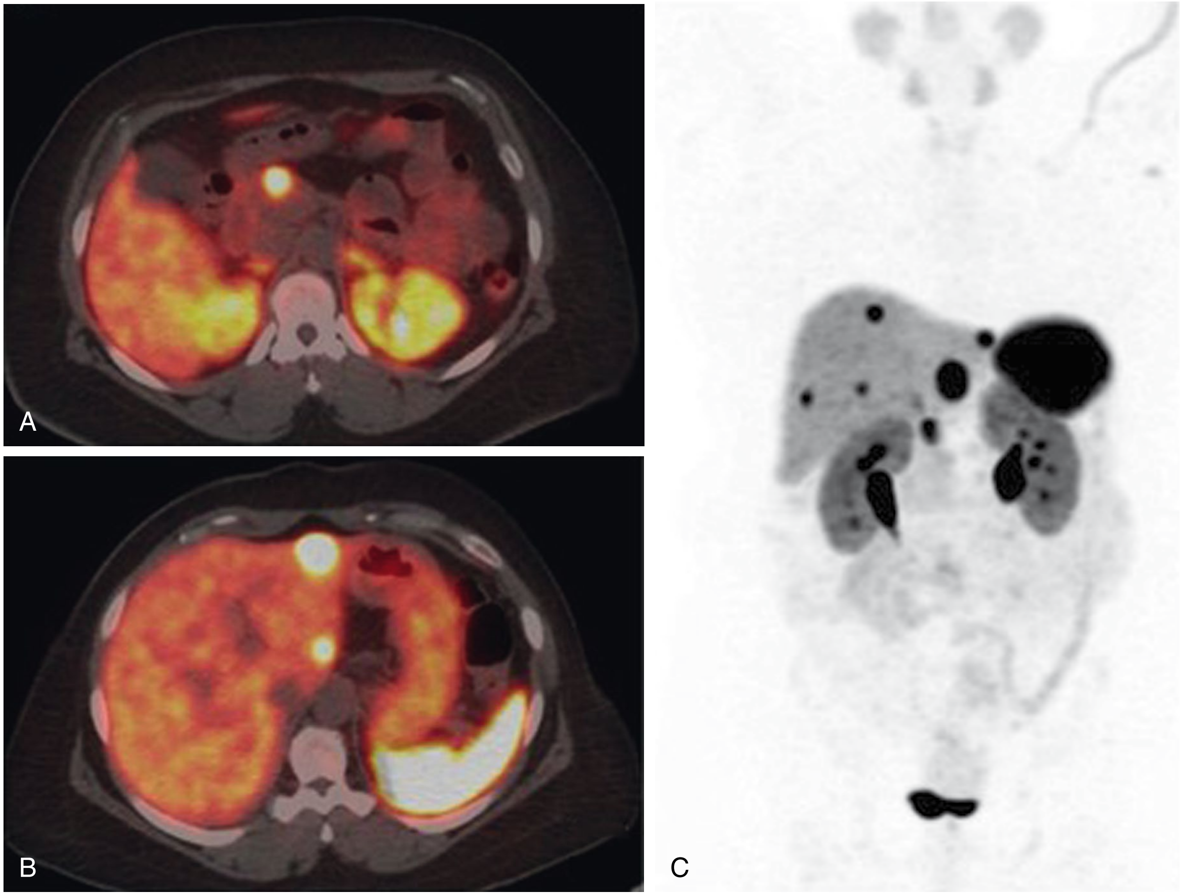


FIGURE 77.2 A 40s-year-old patient with a clinical diagnosis of hypergastrinemia. PET–DOTATATE scan was significant for head-of-pancreas pNET (initially occult on computed tomography scan) and numerous liver metastases (biopsy positive for well-differentiated pNET). (A) Axial cut demonstrating head-of-pancreas hyperintense region. (B) Axial cut demonstrating two of six hyperintense liver metastases. (C) Coronal cut demonstrating head-of-pancreas NET and six liver metastases. *NET,* Neuroendocrine tumors; *pNET,* neuroendocrine tumor of the pancreas;

tricuspid stenosis (42%). Atypical carcinoid syndrome is typically mediated by histamine production. Rarely, type III gastric NETs may cause this with a presentation of flushing that is extremely red, patchy, or pruritic.

Typically, serotonin, tachykinin, and metabolites are removed from systemic circulation by the liver. Therefore, excess secretion is usually clinically silent until liver metastases develop. Those patients with NETs that develop symptomatic carcinoid syndrome portend a worse prognosis than those without (median overall survival 4.7 years compared with 7.1 years). Several metabolites of serotonin may be measured, including 5-HTP, which can be measured in a 24-hour urine collection and may be used to monitor disease progression. 5-HTP can also be elevated in the urine in those without carcinoid syndrome after consuming certain foods. CgA is another well-established biomarker for carcinoid syndrome. It is elevated in more than 80% of patients with NETs.

Chronic carcinoid syndrome is treated by reducing the culprit hormone levels and tumor burden, if able. This includes surgical resection or debulking as well as medical management. Long-acting SSAs such as octreotide are the standard of care, especially in those with unresectable disease, and have been shown to improve progression-free survival as well as quality of life. Those with refractory or progressive disease on SSAs may be trialed on PRRT. This therapy consists of dispensing a radiolabeled SSA therapy such as lutetium-177-DOTATATE (^{177}Lu).

Carcinoid crisis is a severe potential complication in those with uncontrolled carcinoid syndrome. It occurs upon a sudden release of serotonin or other vasoactive metabolites either spontaneously or from either tumor manipulation (biopsy or surgical resection), use of sympathomimetic drugs (amphetamines, albuterol), or upon receipt of cytolytic therapies (hepatic embolization). Patients may present with hemodynamic instability, severe flushing, profuse diarrhea, and ventilation difficulties from diffuse bronchospasm.

Treatment of carcinoid crisis consists of octreotide (both as an IV bolus and continuous infusion), IV fluid resuscitation, corticosteroids, and vasopressors as needed based on patient hemodynamics. Octreotide can also be used as a preventive measure before, during, and after maneuvers that may manipulate the tumor. Although potentially fatal, carcinoid crisis is rare.

- Multiple Endocrine Neoplasia Type 2B
- Medullary Thyroid Cancer
- Pheochromocytoma
- Primary Hyperparathyroidism

Multiple Endocrine Neoplasia Type 4

Conclusion

The multiple endocrine neoplasia (MEN) syndromes are a consequence of genetic alterations that lead to the development of tumors in endocrine organs and tissues. MEN type 1 (MEN1) is caused by a genetic change in menin, a tumor suppressor gene. MEN type 2 (MEN2) is related to changes in the *RET* (REarranged during Transfection) proto-oncogene. MEN type 4 (MEN4) is a rare clinical entity with features similar to MEN1 but caused by a genetic mutation in the cyclin-dependent kinase CDKN1B, a tumor suppressor gene.

Each of the MEN syndromes manifests as a phenotypic expression of different tumors. MEN1 includes pituitary adenomas, parathyroid adenomas in multiple glands, and neuroendocrine tumors (NETs) of the pancreas and gastrointestinal system. MEN1 carriers may also develop thymic carcinoid tumors, lipomas, adrenal adenomas, ependymomas, and angiofibromas.[1] MEN2 is divided into MEN2A and MEN2B. Patients with MEN2A present with medullary thyroid cancer (MTC), pheochromocytomas, and parathyroid tumors. MEN2B is characterized by MTC, pheochromocytomas, mucosal neuromas, marfanoid features, and ganglioneuromatosis of the gastrointestinal tract. Management for these conditions involves screening, surveillance, and medical and surgical intervention.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Epidemiology and Genetics

MEN1 is rare in the general population, with a prevalence of 1 to 3 per 100,000.[2] MEN1 germline mutations are found in 1% to 18% of patients with reportedly sporadic primary hyperparathyroidism (PHPT).[3] Patients with pituitary tumors have MEN1 less than 3% of the time. For NETs, the presence of MEN1 mutations varies based on the type of tumor. The clinical manifestations of MEN1 vary across all ages. In general, clinical evidence of MEN1 develops by 50 years of age in 75% of individuals with MEN1 mutations. There does not appear to be any racial or ethnic predisposition, and autosomal dominance inheritance suggests that MEN1 affects male and female patients equally, though this may vary by subtype of clinically evident tumors.[4,5] Overall survival in MEN1 carriers is difficult to estimate and varies because many series combine patients with similar manifestations of a particular clinical entity. For example, in patients presenting with MEN1-related gastrinomas, survival after 5 and 10 years was 83% and 65%, respectively.[6]

MEN1 is a hereditary syndrome inherited in an autosomal dominant pattern. It develops after a germline mutation and loss of heterozygosity in the MEN1 (menin) gene, leading to the development of tumors. Menin, found on chromosome locus 11q13, functions as a tumor suppressor gene. Tumor suppressor genes regulate cell proliferation and growth. MEN1 mutations often result in a truncated menin protein, which leads to a loss of menin expression.[7]

Genetic cloning was used to identify menin, a 610–amino acid protein.[8] Endocrine and nonendocrine cells express varying levels of menin, which is located primarily in the cell nucleus. In addition to the functions noted earlier, menin has a role as a pro-oncogenic factor in mixed lineage leukemia (MLL) by interacting with MLL-1 fusion proteins to cause leukemia. Also, it has been linked to an increased risk of developing breast cancer, possibly through estrogen receptor regulation.[9]

More than 1600 mutations in the menin gene have been described, and roughly 15% are somatic and 85% are germline.[10] Nearly 70% of MEN1 germline mutations are considered pathogenic, often because of frame-shift mutations (42%), nonsense mutations (14%), or splicing defects (11%).[3] The mutations are spread out over the coding region as opposed to existing in clusters. Around 5% of patients with MEN1 do not have any evident germline mutation within the known coding region, and these may be related to mutations in promoter regions that have not yet been described.

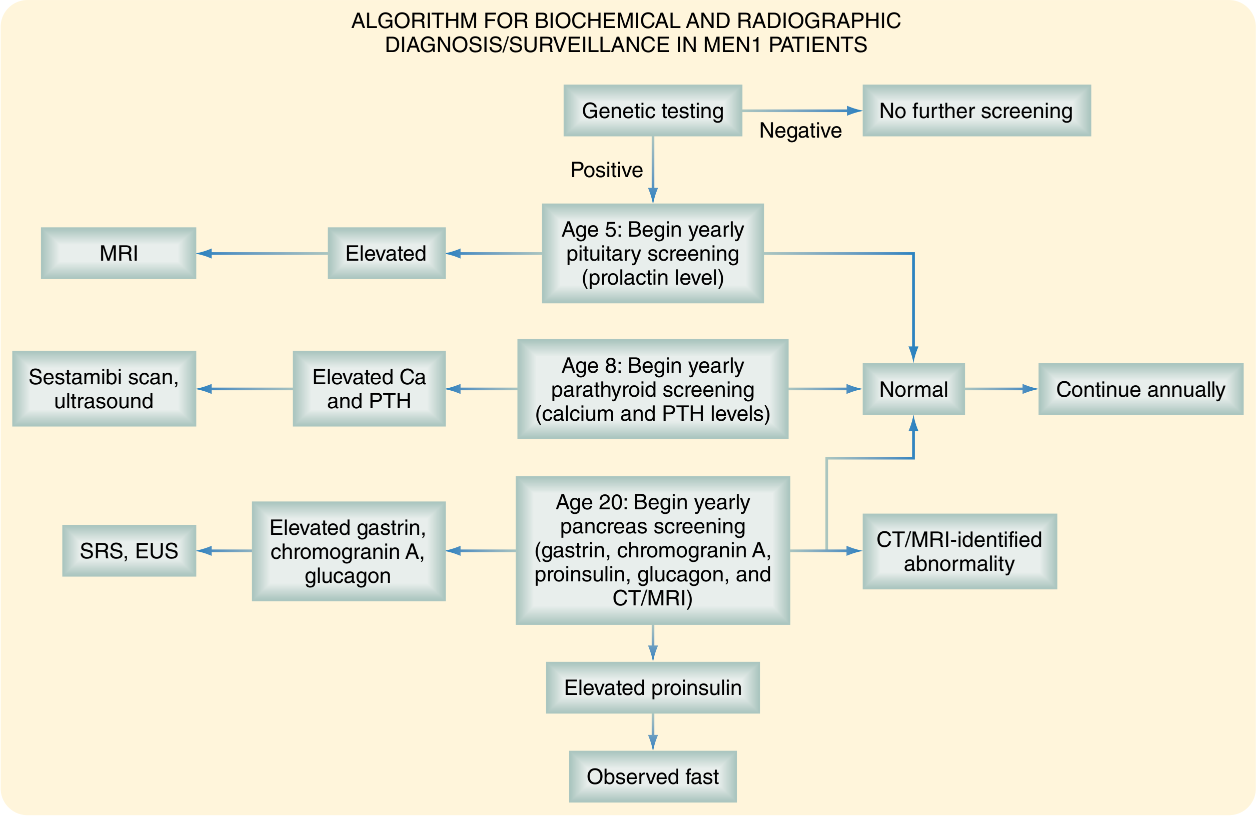
Current clinical practice guidelines recommend that patients suspected to have MEN1 and relatives of patients with known MEN1 receive genetic testing.[11] Asymptomatic relatives should receive MEN1 germline mutation testing because presence and timing of clinical manifestations of the disease vary. Appropriate genetic testing can often help individuals without a mutation avoid unnecessary tumor screening. Around 10% to 20% of individuals with MEN1 may not have a mutation identified. For this reason, the diagnosis of MEN1 is made clinically in patients with two or more MEN1-associated tumors or in a patient with one MEN1-associated tumor and a first-degree relative with MEN1.[3] Regardless of a genetic or clinical diagnosis, all patients with MEN1 should undergo routine screening for various associated tumors. Of note, germline mutations of the *CDKN1B* gene are associated with the development of parathyroid adenomas, pituitary adenomas, and PNETs, and this syndrome is known as *MEN4*. Given the clinical similarity to MEN1, this may account for persons who meet clinical criteria for MEN1 but lack a known mutation of the MEN1 gene. MEN4 is a relatively newer MEN categorization, and investigation is ongoing to better understand this entity.

Clinical Presentation and Management

MEN1 is classically described as an inheritable autosomal dominant disorder that manifests as tumors of the parathyroid, pancreas, and pituitary (3 Ps). The pancreatic tumors represent a subset of the broader category of gastropancreatic NETs that are found in these patients. Patients with MEN1 also have an increased risk of developing NETs, including meningiomas, angiofibromas, carcinoid tumors, and lipomas. The most common presentation (nearly 100% penetrance) of MEN1 involves PHPT.[2] Often characterized as four-gland hyperplasia, these patients actually have multiple parathyroid adenomas in separate glands. In many cases, the PHPT is the initial clinical presentation of the syndrome.

MEN1 affects male and female patients equally and does not appear to have any specific association with race. If left untreated, patients with MEN1 have a 50% probability of death by 50 years of age.[11] Previously, peptic ulcer disease secondary to Zollinger-Ellison syndrome (ZES) led to significant morbidity (e.g., bleeding, perforation, fistula) and mortality in this patient population. Complications from hypersecretion were the main cause of death in patients with MEN1 and ZES. However, the introduction of medications to control gastric acid production (histamine H_2 receptor antagonists and proton pump inhibitors [PPIs]) has dramatically improved control of the disease, and acute and chronic control of acid hypersecretion is possible in most patients.[12]

Signs and symptoms of MEN1 are related to involvement of specific endocrine glands or tissues and are the result of either hormone overproduction or mechanical effects of benign and malignant tumors. Thus, diagnosis of MEN1 often occurs when evidence of hormone excess or tissue involvement produces identifiable clinical manifestations leading to diagnosis of the syndrome or when asymptomatic family members screen positive for a MEN1 mutation. An algorithm for diagnosis and surveillance is demonstrated in Fig. 78.1. Given the rare nature of the disease process, recent literature highlights the lack of high-quality evidence to guide treatment in this specific population. Much of the previous information relies on observational studies.[13] Certain recommendations (screening, surveillance) may expose patients to



ALGORITHM FOR BIOCHEMICAL AND RADIOGRAPHIC DIAGNOSIS/SURVEILLANCE IN MEN1 PATIENTS
Genetic testing
Negative
No further screening
Positive
Age 5: Begin yearly pituitary screening (prolactin level)
Elevated
MRI
Age 8: Begin yearly parathyroid screening (calcium and PTH levels)
Elevated Ca and PTH
Sestamibi scan, ultrasound
Normal
Continue annually
Age 20: Begin yearly pancreas screening (gastrin, chromogranin A, proinsulin, glucagon, and CT/MRI)
Elevated gastrin, chromogranin A, glucagon
SRS, EUS
CT/MRI-identified abnormality
Elevated proinsulin
Observed fast

FIGURE 78.1 Algorithm for screening and management in multiple endocrine neoplasia type 1 *(MEN1)* syndromes. *CT,* Computed tomography; *EUS,* endoscopic ultrasound; *MRI,* magnetic resonance imaging; *PTH,* parathyroid hormone; *SRS,* somatostatin receptor scintigraphy.

ionizing radiation and false-positive results; each clinical decision should weigh associated benefits and risks for the individual patient. Overall, the goal of treatment rests on medical or surgical intervention to control hormonal hypersecretion or tumor spread. Although patients with MEN1 may have multiple types of tissues affected, parathyroid, enteropancreatic, and pituitary tissues are often described.

Parathyroid

PHPT is the most consistently observed feature of patients with MEN1. Similar to the sporadic form of PHPT, patients may present with evidence of diminished bone health (e.g., osteopenia, osteoporosis), kidney and ureteral stones, or general symptoms of fatigue, memory loss, depression, or anxiety. Additionally, many patients may be asymptomatic. The biochemical diagnosis of PHPT involves increased serum calcium levels and inappropriately nonsuppressed parathyroid hormone (PTH) levels. Generally, around 90% to 95% of patients with PHPT present with a sporadic form of the disorder, and 5% to 10% of PHPT is caused by germline mutations. In general, compared with the sporadic form, patients with MEN1-related PHPT present at an earlier age, with an equal male-to-female ratio, and with a greater severity of bone and renal involvement.[14]

Surgical intervention is the standard treatment for patients with symptomatic MEN1 with PHPT. The optimal timing for asymptomatic patients is not known, and surgeon experience and patient preference should be taken into account.[11] Although preoperative imaging (e.g., ultrasound, sestamibi scan, four-dimensional computed tomography [CT]) is often used in sporadic PHPT to identify potential targets for focused resection, these studies may have less utility in MEN1-related PHPT. These imaging adjuncts may help localize ectopically located glands; however, the current MEN1 clinical practice guidelines recommend routine bilateral exploration and identification of all four parathyroid glands.[11]

In general, subtotal parathyroidectomy (SPT) with three and a half gland removal and total parathyroidectomy (TPT) with autotransplantation are viable operative options. In the case of three and a half gland resection, all four parathyroid glands are visualized, and half of the most normal-appearing gland is left in place, with resection of the three other glands. For TPT, all four glands are removed and one is reimplanted, most commonly in the brachioradialis muscle. In both cases, bilateral cervical thymectomy is recommended to remove any intrathymic parathyroid tissue and potentially reduce the risk of MEN1-related thymic cancer. Over the past few decades, SPT has emerged as the more common approach given that there is a lower risk of permanent hypoparathyroidism compared with TPT with autotransplantation.[15] Only about half of parathyroid autotransplantations fully function.[16] The complication of permanent hypoparathyroidism is notable. Patients with chronic hypoparathyroidism are at increased risk of nephrolithiasis, impaired renal function, cataracts, and seizures.[17]

Given the risk of permanent hypoparathyroidism, some surgeons have considered the alternative of a focused single gland excision (SGE) for patients with MEN1. In a prospectively collected cohort of 89 patients with MEN1 who underwent surgery, 43% underwent TPT, 26% underwent SPT, and 31% underwent SGE. After a median follow-up of 112 months, the rates of recurrent PHPT were 4.4% in the TPT group, 10.1% in the SPT group, and 21.3% in the SGE group, and the rates of permanent hypoparathyroidism were 32%, 17%, and 0%, respectively.[18] A systematic review and meta-analysis involving 25 studies and 947 patients with MEN1 comparing less than subtotal parathyroidectomy (LSPT) to SPT identified that the risk of permanent hypoparathyroidism was 4% in the LSPT group and 20% in the SPT group, but the LSPT approach carried more than a fourfold increased odds of persistent hyperparathyroidism.[15] Weighing the risk of hypoparathyroidism against the likelihood of recurrence should be performed in the individual patient, but, in general, SPT is recommended as the first procedure.

Enteropancreatic Neuroendocrine Tumors

For patients with MEN1, the second most common tumors are enteropancreatic NETs. They occur in 55% to 70% of patients, and they may be functional or nonfunctional and benign or malignant.[2] Among various types, functional MEN1 tumors include gastrinomas (most common functional MEN1 tumor), insulinomas, and vasoactive intestinal peptidomas. Management aims to control hormone excess, prevent disease progression, and control symptoms. For functional tumors, hormone levels can be useful to follow over time to determine disease recurrence. For nonfunctional tumors, chromogranin A or pancreatic polypeptide may be useful. Unlike sporadic NETs, there are commonly multiple NETs in patients with MEN1. For functional NETs, screening for patients with MEN1 involves evaluation of gastrin, glucose, insulin, vasoactive intestinal peptide, glucagon, chromogranin A, and pancreatic polypeptide at 6- to 12-month intervals. Any abnormal elevation of these levels warrants further workup with imaging. For certain types of nonfunctional tumors (e.g., pancreatic), there remains debate about the optimal timing of initiating screening through use of imaging modalities (magnetic resonance imaging [MRI] or CT), but screening may start as early as the second decade of life.[19]

Over the past few decades, there have been advances in the quality of existing modalities and development of new imaging methods including gallium-68 somatostatin analog positron emission tomography (^{68}GaSA-PET) and somatostatin receptor scintigraphy (SRS). Imaging helps determine appropriateness of surgery and resectability in the setting of spread to lymph nodes and other organs. Sensitivity and specificity vary with each modality, but a combination of imaging methods can help guide the evaluation and treatment of patients with MEN1.

Endoscopic ultrasound (EUS) can be used to help localize NETs, particularly small tumors of the pancreas. On EUS, pancreatic NETs (PNETs) often present as a hypoechoic, homogeneous mass with well-defined margins. EUS can provide insight regarding vascular invasion or distance from the pancreatic duct and offers the opportunity for biopsy and pathologic confirmation of the diagnosis. CT is often the first-line imaging modality of choice for NET detection and staging. The multiphase CT protocol should include noncontrast-enhanced images. In the noncontrast imaging, PNETs appear isodense to slightly hypodense, well rounded, and have regular margins. After administration of contrast, PNETs often hyperenhance and have slow washout, thus appearing more hyperdense during the portal venous phase. Diagnostic accuracy of CT for PNETs ranges from 69% to 94%.[20]

MRI can provide anatomic information and avoid exposing the patient to ionizing radiation. Thus, for younger patients who may be followed for decades, MRI represents a reasonable modality for screening for NETs or for continued surveillance to follow known tumors longitudinally. MRI is performed in a multiphase fashion with noncontrast, arterial, and portal venous phases. Generally, the sensitivity ranges from 54% to 100% and the specificity ranges from 78% to 100% in detecting PNETs; the sensitivity and specificity increase for larger tumors.[21] On T1 imaging, PNETs appear hypoisointense amidst hyperintense pancreatic parenchyma. On T2 imaging, the lesions are hyperintense, and, similar to CT, these lesions hyperenhance during the arterial phase with slow washout.[20]

Functional imaging tests offer additional insight into enteropancreatic NETs. Various nuclear medicine tests can identify functional lesions that express somatostatin receptors (SSTRs). SSTRs are expressed in many different types of tissue including the pituitary, pancreas, gastrointestinal tract, thyroid, kidney, blood vessels, and peripheral nervous system, and different tumors (e.g., carcinoids, pheochromocytomas, paragangliomas, neuroblastomas) show a wide variety of SSTR expression. The radiotracers used are somatostatin analogues and have a high affinity for specific subtypes of SSTRs. SSTR scintigraphy has a sensitivity that ranges from 40% to 70% and a specificity that ranges from 92% to 100%. Alternatively, ^{68}GaSA-PET CT has a sensitivity ranging from 88% to 93% and specificity ranging from 88% to 95%.[20] This functional PET imaging technique has lower radiation dose and lower liver uptake compared with SRS. Additionally, PET/CT may play a vital role in detecting metastases when other cross-sectional imaging has failed to identify certain lesions. Dual tracer imaging with 68Ga-DOTATATE and 18F-fluorodeoxyglucose (18F-FDG) PET/CT may offer a promising opportunity to help identify local and metastatic NETs and may be able to predict response to treatment.[22]

For patients with MEN1, approximately 50% of functional enteropancreatic NETs that develop are gastrin-secreting tumors called *gastrinomas*. Conversely, 20% of patients with gastrinomas have MEN1. The typical appearance of a gastrinoma is seen in Fig. 78.2. Classically, these patients have ZES, which is characterized by recurrent multiple peptic ulcers, abdominal pain, chronic diarrhea, and gastroesophageal reflux. Providers should maintain a high index of suspicion in patients with recurrent ulcers, multiple ulcers that occur in atypical locations, that fail to respond to usual therapy, or that occur in the setting of PHPT. Diagnosis of ZES requires the presence of both acid in the stomach and elevated fasting serum gastrin levels after the patient has stopped taking acid-suppressive medication (generally 2 weeks off PPIs and 2 days off H_2 receptor antagonists). The diagnosis is definitive if the gastrin level is greater than 1000 pg/mL with gastric acid present (which may be determined by measuring a gastric pH level). Atrophic gastritis (pernicious anemia) can be a confounding diagnosis with elevated gastrin levels, but there is no acid in the stomach. In patients whose levels do not meet the diagnostic threshold, a secretin stimulation test can be performed. Serum gastrin levels are measured at 2 and 15 minutes after intravenous secretin administration, and levels greater than or equal to 200 pg/mL are considered diagnostic of ZES.

The role of surgical management for MEN1-associated gastrinoma remains controversial. Patients with MEN1 often have multiple tumors and nodal metastases, and so the cure rate is relatively low, though the disease is relatively indolent in terms of metastatic disease affecting survival. Medical management with PPIs and H_2 blockers is often deployed given that it is difficult, if not impossible, to cure patients with MEN1 or achieve long-term eugastrinemia. Providers can work with patients to determine their preferences and tailor the surgical approach individually based on malignant behavior and morbidity involved in resection. Of note, in patients with co-occurring PHPT and gastrinoma, parathyroidectomy is recommended because surgical resection has been shown to be associated with decreased basal acid output and lower gastrin levels.[23] Hypercalcemia is associated with an increase in circulating gastrin levels, and parathyroidectomy may help lower calcium and gastrin levels.

Insulinomas are characterized by hypersecretion of insulin causing hypoglycemia. The β-islet cell tumors secrete insulin even when plasma glucose concentrations are low. Hyperinsulinemia leads to decreased gluconeogenesis and increased glycogen synthesis, which contributes to hypoglycemia. Incidence is 1 to 4 per million per year. Around 7% of cases are associated with MEN1 syndrome.[24] Insulinomas represent up to 30% of functional PNETs in patients with MEN1. Patients often present with "Whipple triad," including (1) fasting glucose levels less than 50 mg/dL, (2) symptoms of hypoglycemia (headache, palpitations, confusion, hunger, fatigue), and (3) resolution of symptoms upon administration of glucose. The hypoglycemic episodes are divided into neuroglycopenic and adrenergic categories. Neuroglycopenic symptoms are caused by a reduction in central nervous system glucose supply and lead to impaired cognition, disorientation, memory deficits, and visual disturbances. Adrenergic symptoms are caused by sympathetic nervous system activation and include anxiety, tremor, diaphoresis, and palpitations. Patients often experience symptoms during fasting periods (e.g., upon awakening from overnight fast or during exercise).

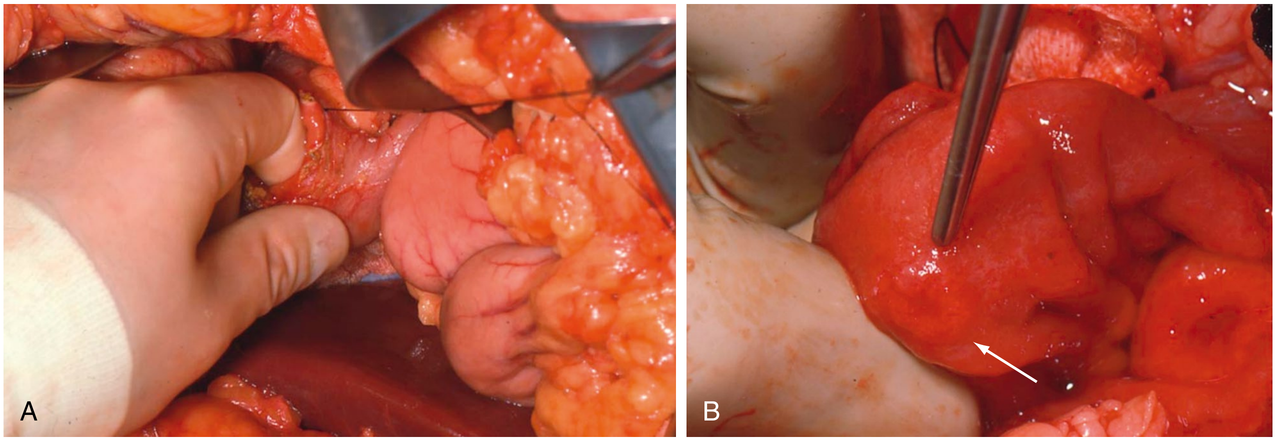


FIGURE 78.2 Gastrinoma, intraoperative findings. (A) Duodenotomy and palpation of the duodenal wall. (B) Typical appearance of a gastrinoma in the duodenal wall, indicated by *arrow*.

The differential diagnosis for patients with hypoglycemia is broad, and it is important to consider alternative explanations when patients present with low blood glucose. Exogenous insulin administration remains high on the differential, and a detailed history should be obtained from the patient to rule out this possible cause. Additionally, oral hypoglycemics, renal failure, liver dysfunction, autoimmune disease (e.g., systemic lupus erythematosus), and multiple myeloma can all contribute to states of insulin biochemical disturbances.[25]

The diagnosis of insulinoma is made during a monitored 72-hour supervised fast during which plasma glucose, insulin, and C-peptide levels are measured every 6 hours. An elevated insulin level with a low glucose level is diagnostic. However, a 48-hour fast may be adequate and as accurate and may replace the 72-hour fast. Oral hypoglycemic agents should be discontinued. To establish the diagnosis, these six criteria may be met: blood glucose $\leq$40 mg/dL, insulin >36 pmol/L, proinsulin $\geq$5 pmol/L, C-peptide $\geq$200 pmol/L, β-hydroxybutyrate $\leq$2.7 mmol/L, and absence of urine or plasma sulfonylurea metabolites.[25]

Insulinomas may be multifocal and occur throughout the pancreas and are best imaged by CT and EUS. They can be difficult to locate and may be identified at operative exploration with or without intraoperative ultrasound, whose sensitivity ranges from 70% to 95%. Fig. 78.3 demonstrates the use of intraoperative ultrasound to identify an insulinoma. Anatomic imaging, including CT, MRI, and EUS, has varying sensitivities—all less than 50%. Arterial calcium stimulation with selective hepatic vein sampling was historically used, but the invasive nature of this test has led to decreased use. Glucagon-like peptide-1 receptor (GLP-1R) imaging offers an alternative less invasive option given that GLP-1R is mainly expressed on pancreatic β cells. Intraoperative aspiration of the lesion and use of a rapid assay for insulin can confirm the diagnosis.

Surgery is the mainstay of treatment for insulinomas, but medical options exist. After confirmation of the diagnosis, many patients may receive diazoxide, which acts on potassium channels on β-pancreatic islet cells and contributes to decrease insulin secretion.[25] Diazoxide can be given in doses of 50 to 300 mg/day, and side effects include congestive heart failure, peripheral edema, renal dysfunction, and weight gain. Diazoxide should be stopped at least 1 week before surgery to avoid intraoperative hypotension. Potential additional medical therapies also include phenytoin, verapamil, streptozocin, and everolimus. Surgical intervention commonly involves enucleation, and this approach is generally used for benign, superficial tumors less than 2 cm. For larger tumors and those with suspicion for malignant features, a formal anatomic resection is often undertaken. Lesions of the distal body and tail undergo distal pancreatectomy, whereas patients with larger insulinomas localized to the head of the pancreas may undergo pancreaticoduodenectomy. In patients with MEN1 with multiple pancreatic tumors, it may be helpful to ensure that the functional tumor is included in the resection using a study such as selective arterial calcium infusion with hepatic vein insulin sampling. The remaining functional tumors (glucagonomas, VIPomas, and somatostatinomas) comprise less than 5% of functional PNETs in MEN1.

Most enteropancreatic NETs in patients with MEN1 are nonfunctional PNETs. These lesions do not have an associated clinical

syndrome and are diagnosed on surveillance imaging or after the development of symptoms related to mass effects of tumor. For patients with MEN1, surveillance for nonfunctional PNETs should begin at age 13 years.[19] Surgical decision-making centers around the need for multiple operations and potential for the development of multiple tumors and metastases. In a systematic review of nonfunctioning PNETs encompassing 13 studies and 370 unique patients, tumor size and grade were the most important prognostic factors.[26] These findings suggest that tumors less than 2 cm can undergo watchful waiting and serial imaging. Higher-grade lesions may be considered for surgical resection regardless of size, though data are insufficient to provide a clear recommendation.[27] Surgical resection is recommended for nonfunctioning PNETs ≥2 cm.

Pituitary Gland

The prevalence of pituitary adenomas in patients with MEN1 ranges from 30% to 60% and often occurs in the fourth decade of life.[28] One percent of patients with pituitary adenomas have MEN1. Patients with MEN1 often present with PHPT before showing clinical evidence of a pituitary adenoma. Pituitary tumors can cause symptoms through hormone secretion or from local effects of the tumor. Most tumors are benign, unifocal, and secrete hormones including prolactin, growth hormone, or corticotropin. In a group of 268 patients with MEN1, 51.8% had pituitary adenomas and 57% of these were functional, most commonly prolactin-secreting adenomas.[28] Screening for pituitary adenomas should include annual prolactin and insulin-like growth factor-1 (IGF-1) measurements beginning at age 5 years and MRI evaluation every 3 years.[29] MEN1-related pituitary tumors are larger and more often secrete multiple hormones (e.g., prolactin and adrenocorticotropin-secreting hormone) compared with the sporadic form. Treatment for pituitary tumors in MEN1 includes both medical and surgical therapy. Medical therapy aims to control hormone excess. Unfortunately, a lower proportion of patients with MEN1 with functional pituitary adenomas achieve normalization of pituitary hormone concentrations compared with the sporadic tumor population. Surgical intervention is reserved for patients who fail to normalize hormone levels after initiation of the appropriate pharmacologic intervention or those who develop symptoms related to mass effect on the optic chiasm.

Other Tumors

Other MEN1-related tumors include carcinoids of the thymus, bronchi, and gastrointestinal tract; adrenocortical tumors; and cutaneous tumors (e.g., lipomas, facial angiofibromas, and collagenomas). Thymic carcinoid tumors are likely to be malignant, aggressive, and have a poor prognosis. Unfortunately, there is not an optimal screening method given the lack of data. Nevertheless, CT and MRI are recommended every 1 to 2 years for earlier detection. Surgery is the preferred treatment. Historically, transcervical thymectomy was thought to prevent thymic carcinoids. However, in a review of 122 patients with MEN1 who underwent cervical thymectomy at the time of parathyroidectomy, only one incidental thymic carcinoid was discovered.[30] Additionally, nine patients developed thymic carcinoid tumors during the follow-up period after a median of 36 months. Thus, preventive transcervical thymectomy is not recommended outside of planned parathyroidectomy, and specific follow-up and imaging protocols may allow for detection of thymic carcinoids. Adrenal tumors are common, and approximately 20% of patients have some adrenal hyperplasia. Compared with incidental adrenal tumors, patients with MEN1 exhibit adrenocortical carcinoma and primary hyperaldosteronism more frequently and pheochromocytoma less frequently.[31] There are no established guidelines for management of adrenal tumors for the MEN1 population. Recommended management is similar to incidental adrenal masses, and surgical resection is indicated for size (≥4 cm), growth, suspicion for malignancy, and excess hormone production.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

MEN2 is an autosomal dominant hereditary syndrome caused by germline mutations in the *RET* proto-oncogene. MEN2 is divided into MEN2A and MEN2B and includes various tumor types (Fig. 78.4). MEN2A classically presents with MTC, pheochromocytoma, and PHPT. MEN2A can be further subclassified into specific phenotypes including classical MEN2A, MEN2A with cutaneous lichen amyloidosis, MEN2A with Hirschsprung disease, and familial MTC. MEN2B is characterized by MTC, pheochromocytoma, ganglioneuromas, and marfanoid features. In the following sections, the genetics, clinical presentation, and management of MEN2 are detailed.

Epidemiology and Genetics

The prevalence of MEN 2A and MEN2B is approximately 20 and 2 per million, and the incidence for these two entities ranges from 8 to 28 and 1 to 3 per million live births, respectively.[32] The *RET* proto-oncogene is located on chromosome 10q11.2 and codes for a tyrosine kinase membrane receptor. Each of the MEN2 syndromes occurs as a result of a *RET* germline mutation. Mutations that result in the development of MTC are missense mutations that cause a gain-of-function mutation. The *RET* protein is formed by an extracellular ligand-binding domain, a transmembrane domain, and a cytoplasmic tyrosine kinase domain (Fig. 78.5). The intracellular tyrosine kinase subdomains are involved in intracellular signal transduction pathways. Unlike other receptor tyrosine kinases, *RET* activation occurs through a multiprotein ligand complex as opposed to direct receptor ligand interaction.[32] Activation of the *RET* complex results in *RET* dimerization and promotes cell signaling, differentiation, growth, and survival. Specific mutations in *RET* can result in unregulated gene activation and tumor development.

RET participates in a number of cell signaling pathways and is expressed in multiple neural crest tissues, including thyroid parafollicular cells (C cells), parathyroid glands, adrenal chromaffin cells, enteric ganglia, and peripheral and central neurons. Mice with mutated *RET* genes have renal agenesis and lack neurons throughout the digestive tract, suggesting that *RET* also plays a role in renal and neuronal development. Inactivating *RET* mutations are associated with Hirschsprung disease in humans, a defect in the development of enteric neurons resulting in megacolon and constipation in infancy. Unlike MEN1, strong genotype-phenotype correlations exist in MEN2, and specific *RET* mutations can predict the onset and aggressiveness of the disease. Prophylactic thyroidectomy is offered to improve survival. Patients with reportedly sporadic MTC may carry *RET* mutations, and they should be offered genetic testing.

For patients with MEN2 clinical presentation, the standard of care includes sequencing of the *RET* gene to identify germline mutations. Providers can anticipate and test for involved coding regions related to the MEN2 type known to the kindred or suspected based on clinical findings. All offspring of known kindreds should be offered genetic counseling and genetic testing early in

life.[33] In certain cases, the presenting tumor known to occur within MEN2 may be the first evidence of the syndrome. Further, some presentations may occur as de novo mutations, and the absence of family history should not preclude testing. Additional recommendations for testing include infants or young children with Hirschsprung disease, parents whose infants or children have the physical phenotype of MEN2B, and patients with cutaneous lichen amyloidosis.[33]

CLINICAL PRESENTATION AND MANAGEMENT

Multiple Endocrine Neoplasia Type 2A

MEN2A is the most common subtype of the MEN2 syndromes, comprising the majority of cases (95%). The hallmark characteristic of MEN2A is the development of MTC in nearly 100% of patients, though there are mutations with lower or later in life penetrance patterns. In addition to MTC, pheochromocytoma develops in 30% to 50% of patients and PHPT in up to 5% to 15%.[32] The degree of penetrance of each tumor type is associated with specific codon mutations, and all patients are at risk for the development of multiple tumors.

MEN2A contains four subclassifications: classical MEN2A, MEN2A with cutaneous lichen amyloidosis, MEN2A with Hirschsprung disease, and familial MTC (FMTC). Cutaneous lichen amyloidosis is uncommon and typically occurs with codon 634 mutations. It is characterized by the symptom of pruritus, and it is thought that repeated scratching leads to amyloid deposition in the papillary dermis of the skin. As a result, patients develop cutaneous plaques, often located on the back. In this group, the prevalence of MTC, pheochromocytoma, and PHPT is 95%, 50%, and 5%, respectively.[32] Hirschsprung disease may also occur in patients with MEN2A. The disease is characterized by the congenital absence of ganglion cells within the myenteric and submucosal plexus of the distal colon. In newborns, the presentation often includes abdominal distention, constipation, and megacolon that occurs because of aganglionosis. In patients with MEN2A/Hirschsprung disease, there are mutations in codons 609, 618, or 620. In these kindreds, nearly 20% have Hirschsprung disease, and patients with MEN2A should be counseled regarding the possibility of the disease in offspring. Hirschsprung disease occurring outside of the setting of MEN2A is from inactivating, or loss-of-function, *RET* mutations. Hirschsprung disease affects approximately 7% of patients with MEN2A overall. In this group, the prevalence of MTC, pheochromocytoma, and PHPT is 77%, 17%, and 3%, respectively.[32]

Over time, multiple definitions of FMTC have emerged. FMTC is characterized by the identification of a *RET* mutation in families with MTC with no history of pheochromocytoma or PHPT. Although all patients ultimately develop MTC, on average, they are diagnosed in their mid-40s, approximately 20 years later than MTC associated with MEN2A. Multiple *RET* germline variants of different codons (e.g., 533, 768, and 804) are associated with FMTC. Many of the common variants are able to cause pheochromocytoma or PHPT, which makes it difficult to distinguish between classic MEN2A and FMTC.[32]

Multiple Endocrine Neoplasia Type 2B

Approximately 5% of MEN2 cases fall within the classification of MEN2B. As in MEN2A, the hallmark characteristic of MEN2B is the development of MTC. Approximately 50% of patients with MEN2B develop pheochromocytomas. Patients with MEN2B have a characteristic appearance with elongated facies, a marfanoid body habitus, ophthalmologic and skeletal abnormalities (e.g., pectus excavatum and scoliosis), and mucosal neuromas of the lips and tongue. Ganglioneuromatosis throughout the gastrointestinal tract contributes to esophageal dysmotility, abdominal bloating, intermittent constipation, and diarrhea. MEN2B often develops in infancy and tends to be aggressive with early metastasis. The majority of patients with MEN2B have germline mutations in exon 16, codon M918T, whereas less than 5% have mutations in codon A883F. MTC is the cause of death in approximately 65% of patients with the M918T variant.[34] Those with A883F mutations may have a milder, less aggressive form of MTC.

Medullary Thyroid Cancer

MTC represents less than 5% of all thyroid cancers.[32] Unlike papillary and follicular thyroid cancers, MTC arises from the parafollicular C cells, which produce calcitonin. Treatments such as suppression of thyroid-stimulating hormone and radioactive iodine (RAI) are not used, as C cells are not sensitive to these therapies. Approximately 25% of MTC is familial, and C-cell hyperplasia precedes the development of MTC. Although MTC may present as an indolent malignancy, there are distinct differences in outcomes among different codon mutations. In a German single-center database of 263 patients with MTC who underwent an operation, overall 10-year survival was 76.%, 94.3%, and 89.9% in the highest risk (codon 918), high (codons 634 and 883), and moderate risk (all other *RET* mutations) groups, respectively.[35] Independent predictors of worse disease-specific survival were increasing age, stage III/IV at diagnosis, and highest-risk group designation. Within MEN2A, the time of onset of MTC differs among genotypes, although the survival is the same once MTC is diagnosed.[36]

Once clinically apparent, MTC may present as a central neck mass. Symptoms from local effects such as compression or hoarseness may be present because of tumor invasion. MTC may be multifocal, and total thyroidectomy is recommended—certainly in those individuals harboring a germline mutation. Diagnosis can be made with fine-needle aspiration biopsy, and, in addition to the presence of parafollicular cells and staining for calcitonin, the tissue has amyloid staining properties in most cases. Importantly, amyloid goiter secondary to amyloid light chain amyloidosis can also present with amyloid deposits within the thyroid, but this is rare.[37] Nearly half of patients have lymph node metastases if the diagnosis is made clinically rather than based on calcitonin levels. Evaluation for lymph node disease should be done, including the central compartment (level VI) and the lateral compartment (levels II, III, IV, and V). MTC with distant metastases (outside of the neck) is considered incurable. Nearly 20% of patients with MTC with a palpable neck mass have metastases at diagnosis. In a single-center study, the most common sites of metastasis were lung (52%), bone (28%), and the mediastinum (20%).[38]

C cells secrete calcitonin, which is a useful surrogate marker for both diagnosis and recurrence as calcitonin is produced by nearly all MTC. Historically, provocative testing for calcitonin with pentagastrin was performed as a screening test; however, pentagastrin is no longer available in the United States. Most MTCs produce carcinoembryonic antigen (CEA), and CEA levels are often helpful for monitoring patients. However, CEA can be normal in advanced disease so it may play a limited role.[39]

Ultrasound is the most sensitive method of imaging the neck in patients with primary, persistent, or recurrent MTC and is useful for obtaining fine-needle aspiration biopsies of either thyroid nodules or suspicious-appearing lymph nodes in the neck. CT of the neck may be useful in planning surgery with apparently bulky disease. CT and MRI may be used to evaluate for metastatic disease for the chest and abdomen. In some cases of MTC, the tumor expresses SSTRs, and ^{68}Ga-DOTA-somatostatin analogue PET/CT may offer additional information regarding sites of disease. However, the prevalence of tumor avidity on these imaging scans may be low in the setting of metastatic disease.[40]

Surgery for Medullary Thyroid Cancer

Surgery for MTC in patients with MEN2 occurs in one of two settings: (1) to resect clinically apparent disease diagnosed by the finding of a biopsy-proven thyroid cancer or cervical malignant lymphadenopathy or (2) to prevent potential tumor development or spread in the prophylactic setting. For patients with clinically evident disease, preoperative workup includes a biochemical evaluation (calcitonin and CEA) as well as imaging to determine the extent of tumor involvement. Depending on preoperative calcitonin level, workup may also include cross-sectional imaging of the chest, abdomen, and pelvis to evaluate for distant metastases. Additionally, preoperative plasma or 24-hour urine metanephrines is necessary to exclude the possibility of a concomitant pheochromocytoma. If discovered, surgery for pheochromocytoma should precede thyroidectomy.

Total thyroidectomy should be performed in all patients with hereditary MTC because approximately 90% of patients with a familial form of MTC will have bilobar, multifocal disease. The initial operation should include a bilateral central (level VI) lymph node dissection given that the rate of lymph node metastases to level VI is high.[41] Additionally, reoperation carries higher risks of recurrent laryngeal nerve injury and hypoparathyroidism. Both the ipsilateral and contralateral lateral nodal compartments (levels II–V) are also frequently involved. The occurrence rates of lateral node metastases depend on primary tumor size as well as extent of involvement of the central compartment, and preoperative calcitonin and CEA levels can positively correlate with the presence of lateral node metastases.[33] Guidelines recommend a patient-tailored approach when considering lateral neck dissection at the time of the initial operation because the compartment is anatomically separate from the central neck. Careful attention should be paid to the identification of the parathyroid glands at operation. Ideally, they should be maintained in situ, but in situations where this is not possible, they may be autotransplanted into either the sternocleidomastoid muscle or to the brachioradialis muscle of the forearm depending on the likelihood of developing PHPT.

The goal of preventive surgery in patients with *RET* mutations is to limit the potential for metastatic spread of MTC and to improve overall survival. Improved survival is linked to performing thyroidectomy and central node dissection when calcitonin levels are either undetectable or very low and when there is no clinically apparent MTC. Therefore, preventive thyroidectomy is recommended in infants, children, and adolescents, and recommendations are stratified according to the mutation present.[33]

In the 2015 American Thyroid Association (ATA) guidelines, the management of MTC was updated.[33] Moderate-risk carriers (ATA-MOD) include all *RET* mutations other than M918T, C634, and A883F, and these individuals should begin annual screening with physical and ultrasound examination as well as calcitonin measurements done at 6- to 12-month intervals beginning at the age of 5 years. The timing of thyroidectomy can then be determined using calcitonin levels. The follow-up period in this group may extend for several years, and there is potential for loss of continuity, and these factors should be considered when timing preventive surgery. Those in the ATA-H risk category (C634 or A883F mutations) should be considered for a preventive thyroidectomy performed at the age of 5 years, or earlier if serum calcitonin levels dictate otherwise. Inclusion of central lymph node dissection at the time of total thyroidectomy is based on preoperative calcitonin levels as well as intraoperative inspection of lymph nodes. For the ATA-HST risk category (M918T), patients should have a total thyroidectomy within the first year of life. Surgeons may perform central lymph node dissection at the initial operation based on the presence of clinically suspicious level VI lymph nodes and their ability to identify and preserve parathyroid glands.[31] Children operated on at an earlier age are more likely to have a biochemical cure and improved survival. In a cohort of 345 patients with MEN2B, early thyroidectomy (before 1 year) was compared with post–1 year thyroidectomy, and 83% of patients who underwent early thyroidectomy were in biochemical remission compared with 15% in the post–1 year group.[34]

Outcomes for patients with MTC are largely dependent on the age and stage at the time of surgical management. Ultimately, carriers of *RET* mutations require lifelong follow-up not only for detection of recurrent MTC but also to monitor and adjust thyroid hormone levels after total thyroidectomy. Calcitonin and CEA levels should be measured 3 to 6 months postoperatively, and future cadence of follow-up based on this result and subsequent doubling time of calcitonin and CEA.

Recurrent and Metastatic Disease

Approximately 50% of patients with MTC have either persistent or recurrent disease after initial operation. After surgery, these patients are identified by physical examination (e.g., palpable neck mass), rising calcitonin levels, or radiographic abnormalities. Depending on the degree to which calcitonin rises, distant metastatic disease should be considered and evaluated. Regional recurrences limited to the neck are best managed with repeat operation versus continued observation for small-volume stable disease. Reoperative neck surgery should be focused on treating compartments with imageable or biopsy-proven disease, with the operation done in a compartment-oriented fashion for previously nonoperated compartments.

Historically, limited options beyond surgery existed for management. Postoperative RAI is not indicated. External beam radiation therapy and traditional chemotherapy are of limited benefit for the management of recurrent disease in the neck. Recently, targeted therapies involving tyrosine kinase inhibitors have emerged as potential agents for metastatic MTC and *RET*-fusion thyroid carcinomas. Vandetanib and cabozantinib are oral agents that target *RET*, vascular endothelial growth factor (VEGF), and epidermal growth factor receptor (EGFR). In a trial of 331 patients, the median progression-free survival was 21.4 months in the vandetanib group compared with 8.4 months in the placebo group.[42] In this trial, nearly 36% of patients receiving vandetanib required dose reductions, often because of side effects. More recently, specific *RET* kinase inhibitors have emerged (e.g., selpercatinib, pralsetinib), and these agents appear to have fewer side effects and have demonstrated notable responses for MTC patients.[43,44] A clinical trial comparing the progression-free survival of selpercatinib versus vandetanib is ongoing and may soon offer evidence to support certain systemic treatments in *RET* mutant MTC.[45]

Pheochromocytoma

Pheochromocytomas are tumors arising from the chromaffin cells of the adrenal medulla (Fig. 78.6). These cells secrete catecholamines, which are produced in excess in the setting of a pheochromocytoma. The typical clinical presentation includes sweating, tremulousness, headache, flushing, palpitations, anxiety, and episodic hypertension. Typical age at diagnosis is in the fourth or fifth decade of life. Identification of a pheochromocytoma before surgical management of MTC is critical to avoid intraoperative hypertensive crisis and stroke or death. If a pheochromocytoma is identified, then in almost all situations, an adrenalectomy would be performed first to normalize catecholamine levels before thyroidectomy.

Compared with sporadic pheochromocytomas, MEN2-associated pheochromocytomas occur in younger patients, are often bilateral, and have higher baseline metanephrine levels. In a series of 345 patients with MEN2B, 50% presented with bilateral pheochromocytomas by age 30 years, and a similar penetrance was found for patients with MEN2A *RET* 634 codon by age 40 years.[46] Overall, penetrance is dependent on the specific *RET* mutation. MEN2 pheochromocytomas tend to be benign, but given the potential for recurrence and bilaterality, patients require lifelong monitoring. Pheochromocytomas can be malignant, but this is uncommon, occurring less than 5% of the time.[46]

Screening recommendations are stratified by the ATA risk categories, where highest-, high-, and moderate-risk patients begin screening at the ages of 11, 11, and 16 years, respectively.[33] Measurements of plasma free metanephrines and normetanephrines or 24-hour urinary metanephrines and normetanephrines should be done annually, at a minimum. If elevated levels are identified, imaging should be done with either CT or MRI of the abdomen to evaluate for the presence of an adrenal mass.

Patients confirmed to have a pheochromocytoma should undergo surgical resection. Patients should receive preoperative α-blockade to minimize the risk of intraoperative hypertensive crisis. The procedure of choice for operative management is either a laparoscopic or retroperitoneoscopic adrenalectomy, and the selection of the procedure depends on the expertise of the surgeon. The safety of either of these procedures is well established. Minimally invasive adrenalectomies are associated with a shorter hospital stay and less postoperative pain compared with open adrenalectomy. Laparoscopic transabdominal adrenalectomy may be better for larger lesions. If there is any radiologic concern for malignancy (e.g., invasion of adjacent organs or structures), an open adrenalectomy is preferred.

A major concern surrounding operation for MEN2 pheochromocytoma is that it is likely to either be bilateral or recur over time, and patients will potentially need multiple operations. When possible, a cortical-sparing or partial adrenalectomy should be performed to avoid permanent adrenal insufficiency. Situations where cortical-sparing adrenalectomy is preferred include patients who have had the contralateral adrenal gland removed and small tumors where there is a portion of normal-appearing adrenal gland that could potentially be left in situ. Treatment plans should be individualized, and the decision to perform a cortical-sparing adrenalectomy should be weighed against the risks of developing another pheochromocytoma over the patient's lifetime.

Primary Hyperparathyroidism

Debate exists about the prevalence of PHPT in the MEN2 population given different definitions of PHPT across studies. Approximately 8% to 35% of patients with MEN2A may develop PHPT, though the likelihood of development may be based on which mutation is present.[47] PHPT tends to occur earlier and is commonly seen in patients with codon 634 mutations. The recommended age at which screening and annual surveillance should begin follows the recommendations for pheochromocytoma. Moderate- and high-risk-category patients should begin annual testing of calcium and PTH levels at the ages of 11 and 16 years, respectively.[33]

Options for surgical management are similar for patients without MEN2 and include focused parathyroidectomy (removal of abnormal-appearing glands), SPT, and TPT with autotransplantation. Over time, the surgical management of PHPT in the setting of MEN2A has evolved to focus on only removing abnormal-appearing glands and monitoring intraoperative PTH levels.

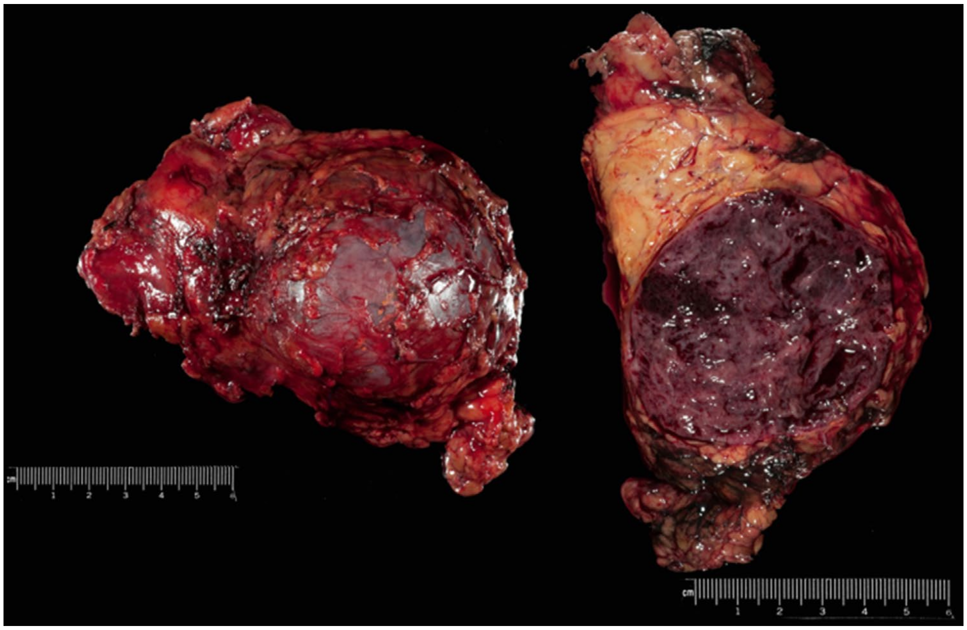

FIGURE 78.6 Resected pheochromocytoma specimen.

The rate of both persistent and recurrent disease is low even with focused or image-guided parathyroidectomy. In planning for a focused parathyroidectomy, preoperative imaging should be obtained. Patients who develop PHPT after a thyroidectomy for MTC should have imaging before undergoing reoperative neck surgery to localize the abnormal gland or glands.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 4

MEN4 is a rare and more recently categorized group of the MEN syndromes. Classically, MEN4 shares clinical similarity with MEN1, and patients present with PHPT, pituitary adenomas, and NETs. However, MEN4 differs from MEN1 in that patients often present at an older age and with milder clinical features.[48] In 2002, a novel MEN syndrome was identified in rats and labeled as MENX. Subsequent studies in humans identified that the *CDKN1B* tumor suppressor gene encoded the cell cycle inhibitor p27, and analysis of patients with MEN1 who had tested negative for germline MEN1 mutations identified *CDKN1B* mutations in a subset of this group. Subsequently, MEN4 was recognized as its own clinical entity in 2007.[48]

Thus far, approximately 80 cases have been identified in the literature. The estimated prevalence is fewer than one per million. The *CDKN1B* gene codes for p27, which acts as a tumor suppressor. When p27 binds cyclin-dependent kinase subunit CDK4, the retinoblastoma protein cannot undergo phosphorylation and the cell cycle is arrested.[49] Studies suggest p27 may play a role in cell cycle progression, cellular migration, and mitotic spindle stability. Additionally, menin may epigenetically modulate *CDKN1B* expression, though further studies are needed to determine whether these associations are drivers or consequences of tumor development.[48]

Similar to MEN1, patients with MEN4 often present with PHPT (>90% of cases), and this is often the first manifestation. The mean age at diagnosis is in the fifth decade of life. Approximately 40% of patients with MEN4 have evidence of pituitary adenomas, with the mean age of onset in the fourth decade of life. Although prolactinomas are the most common subtype (65%) of pituitary tumors in patients with MEN1, adrenocorticotropin hormone (ACTH)–secreting pituitary tumors are more common in patients with MEN4 (40% of all pituitary tumors as compared with 5% in MEN1).[48] NETs are less frequent, occurring in 20% of patients with MEN4 compared with 50% of patients with MEN1.[50] Similar to MEN1, the most common type of functional NET for patients with MEN4 is a gastrinoma.

There is no consensus or widely recognized guidelines for screening, surveillance, or management of patients with MEN4. All patients with clinical evidence of MEN1 should be tested for MEN1. If these tests are negative, patients may have MEN4 and should undergo next-generation sequencing to investigate a germline mutation in *CDKN1B*. Given the paucity of cases and limited existing literature, it is difficult to determine optimal timing of screening or surveillance or to provide definitive recommendations on medical or surgical intervention. In general, guidelines for patients with MEN1 are adopted or modified to help guide treatment in this patient population.

CONCLUSION

Over time, management of MEN has evolved, and our understanding of the natural history and underlying genetic mutations has helped predict the course of the disease and tailor care to the individual patient. Patients with MEN1 can be offered treatment for hyperparathyroidism and appropriate surveillance to avoid sequelae of malignant progression of NETs. Patients with MEN2 may be offered preventive surgery and be cured of MTC. More recently, patients with MEN4 may benefit from identification of the underlying mechanism and placed within their own unique group as we work to better understand screening, surveillance, and treatment in this population. Exclusion of the presence of a mutation in known kindreds can avoid lifelong unnecessary testing. Over time, surveillance and treatment will be tailored to each patient as more is learned about the pathogenesis of these diseases.

Summary

INTRODUCTION

There is wide variation in the incidence of complications in abdominal wall surgery because of the heterogeneity of the patient's comorbidities, hernia characteristics, and surgical techniques. Managing complex hernias and patients with multiple comorbidities is challenging as they are at increased risk of complications.

Studies have shown that patients with ventral hernia who develop complications are at increased risk of developing a hernia recurrence and requiring a reoperation.[1] Developing a complication not only affects patients perioperatively but can also negatively affect a patient's long-term quality of life.[2] Therefore, it is paramount to prevent patients from entering a vicious cycle of complications and strive for the best outcomes at the index repair.

Preoperative optimization emerged as a strategy to identify and intervene upon modifiable risk factors that can negatively affect hernia repair outcomes. Being able to optimize patients and minimizing the effect of some of these variables can not only promote long-term health and provide benefits beyond the perioperative period but can also be a valuable opportunity to motivate and involve the patient in their medical care.

Although it is reasonable to assume that healthier patients will have better outcomes, implementing prehabilitation programs is challenging and requires significant institutional, surgeon, and patient efforts. Additionally, while striving for preoperative optimization, the hernia surgeon should not lose sight of the balance between motivating patients for improved health and hard cutoffs that often unnecessarily delay surgical intervention. Ultimately, preoperative optimization is nuanced, and a one-size-fits-all approach is likely not realistic and, at times, detrimental. In this chapter, we review the evidence behind preoperative optimization, focusing on the main changes that are thought to affect postoperative outcomes in patients with hernia and recognize the current limitation of this field's widespread application to patients who require complex abdominal wall reconstruction.

SURGICAL RISK ASSESSMENT

Introduction

During the first preoperative visit, performing a complete history and physical to adequately identify modifiable risk factors that can be targeted with preoperative optimization is paramount. With the recent advancement in technology and artificial intelligence, surgical risk assessment is an area of exponential interest, and several tools have emerged to assist surgeons in assessing preoperative risk.

Outcomes

The American College of Surgeons (ACS) Universal Surgical Risk Calculator used data from a large database (National Surgical Quality Improvement Project [NSQIP]) and was one of the first tools developed to assess surgical risk using several patients and operative characteristics in a wide range of surgical procedures.[3] One of the main drawbacks of this tool is the lack of granular hernia information and operative techniques, limiting its applicability to patients with hernia.

Given these limitations, other surgical risk calculators were developed for patients with hernia, like the Carolinas Equation for Determining Associated Risks Application (CeDAR) and the Outcomes Reporting App for Clinician and Patient Engagement (ORACLE). The CeDAR app was developed using prospectively collected data from a hernia-specific registry from a single center and can be assessed on smartphones, allowing ease of patient participation during surgical risk discussions.[4] However, it is essential to highlight that the CeDAR app was developed for patients undergoing open ventral hernia repair (VHR) and when reporting complications can be misinterpreted. The CeDAR app reports complications as a composite score and, in essence, reports the overall complication rate, including minor and major morbidity events, which can overestimate actual surgical risk for an individual patient.

The ORACLE risk calculator was developed using a large, national, hernia-specific database (Abdominal Core Health Quality Collaborative [ACHQC]) with more than 10,000 patients undergoing elective VHR with mesh, regardless of operative approach (open, laparoscopic, or robotic). This software can also be downloaded on smartphones, allowing more effortless patient engagement and shared decision-making.[5] This app has the advantage of reporting more granular complications including specific wound events (surgical site occurrence [SSO], surgical site infection [SSI], and SSO requiring a procedural intervention), readmissions, and hernia recurrence. However, the data are reported with confidence intervals (CIs) for more accurate representation, which may be confusing for patients to interpret.

Recommendations

The use of risk assessment tools can assist surgeons and patients in assessing surgical risk and motivate patients to pursue preoperative optimization by allowing them to visualize the impact of preoperative strategies in minimizing surgical risks.

PHYSICAL ACTIVITIES AND PREHABILITATION PROGRAMS

Introduction

Functional activity is strongly correlated with favorable outcomes postoperatively, which is one of the main rationales for pursuing preoperative optimization. Prehabilitation is defined as preoperative methods focusing on improving a patient's functional capability to withstand any postoperative inactivity, functional decline, or eventual postoperative complication. Although some studies suggest a possible benefit with prehabilitation, most have heterogeneous design or lack statistical power, and even fewer include patients undergoing hernia repair.

Outcomes

The PREHAB study, an international, multicenter, randomized controlled trial (RCT), evaluated the effect of a 4-week supervised prehabilitation program in 269 patients undergoing colorectal cancer surgery and found fewer severe complications and medical complications in patients randomized to prehabilitation.[6] In this trial, patients underwent supervised physical training with 1-hour sessions three times a week incorporating aerobic and strength exercises, nutritional interventions supervised by a registered dietitian, anxiety-coping interventions provided by psychology-trained personnel, and a smoking cessation program if indicated.[6] Although the results of this trial are impressive, the amount of time, effort, and ancillary support can be overwhelming for many hernia practices.

In one of the few randomized trials evaluating prehabilitation in VHR, 118 patients were randomized to standard counseling or a prehabilitation program involving a nutritionist and physical therapist with weekly group meetings, daily checklist evaluating nutrition, and exercise program including a DVD with different physical activities.[7,8] In contrast to the PREHAB trial, this study provided access and training information rather than a formal supervised exercise program. Although the early results of the trial showed a lower rate of hernia-free and complication-free rates with prehabilitation, this was not observed in the 2-year follow-up study that showed no difference in hernia-free and complication-free patients between the groups (72.9% vs. 66.1%, $p = 0.42$).[7,8] Interestingly, patients who completed the prehabilitation program did not have sustained weight loss, and approximately half of patients in both groups gained weight from baseline. It is also important to highlight that five patients in the prehabilitation group (8.5%) and one patient in the standard counseling group (1.7%) underwent emergent hernia repair for acute incarceration during the study period.[8]

A large database study using the ACHQC found on multivariable analysis that higher patient-reported exercise level was associated with lower odds of postoperative complication and readmission.[9] However, even patients who reported only sporadic physical activity (once a month) had lower odds of complications and readmissions when compared with patients with no reported physical activity.[9] This highlights that any level of preoperative physical activity may affect postoperative recovery and benefit patients.

Recommendations

Growing evidence in general surgery literature supports prehabilitation programs that include physical activities, especially supervised exercise programs, which can provide better postoperative outcomes. However, few studies evaluate preoperative physical activity programs in patients undergoing abdominal wall surgery. Although there is great potential in implementing these programs, a lot of resources and effort are necessary to implement prehabilitation programs. It remains important to stress to patients in clinic that they can still perform exercise as tolerated because most patients are hesitant to undergo any level of exercise due to the fear of making their hernia larger. A significant amount of time is also necessary to achieve meaningful results through prehabilitation programs, which significantly delays surgical intervention and may increase the risk of a surgical emergency such as acute incarceration, obstruction, or strangulation. Given that the data are still limited, further studies are still required to justify the implementation of prehabilitation programs in patients undergoing hernia repair.

BODY MASS INDEX AND WEIGHT MANAGEMENT

Introduction

The prevalence of obesity is increasing yearly; nearly half of Americans will be obese by 2030, and 1 in 4 Americans are expected to have a BMI >35 kg/m^2.[10] Several studies have linked a higher BMI with an increased risk of hernia recurrence and wound complications in patients with abdominal wall hernias.[11–13] However, most studies identifying this trend include patients with mostly open repair and used large databases or systematic reviews and meta-analyses lacking substantial hernia-specific details.

Although BMI is the most common measurement of obesity, it can be quite inaccurate, particularly in patients with high muscle mass and extremes of height. A Belgian statistician (Lambert Adolphe Francois Quetelet) developed the BMI in the 19th century, and it has proven to have great value when evaluating large populations and public health trends.[14] However, given that patients can have different adipose tissue distribution and different phenotypes of obesity, BMI accuracy is limited when applied at an individual level. Recently, volumetric measurements on CT have emerged as a valuable tool to estimate the impact of obesity on postoperative outcomes. Schlosser et al. measured the abdominal subcutaneous fat volume in preoperative CT scans of patients undergoing open VHR and found that it was associated with the need for panniculectomy, readmissions, and wound complications.[15]

Kaoutzanis et al. used the NSQIP database including 25,172 patients undergoing VHR and found that BMI >30 kg/m^2 was a significant predictor of postoperative SSIs (odds ratio [OR] 1.49); however, open surgery was the strongest risk factor with OR 3.54.[11] It is essential to highlight that most of these studies lack important details, such as granular hernia and operative technique details, which can affect complication and recurrence rates.

The operative approach is an important consideration during operative risk assessment. Minimally invasive surgery (MIS) significantly reduces wound morbidity in obese patients undergoing hernia repairs.[11,16] Given that obese patients are at increased risk of wound complications, minimally invasive repairs can be particularly useful in obese patients, and the International Endohernia Society (IEHS) guidelines currently provide a grade A recommendation, suggesting that MIS techniques should be preferred in obese patients.[17] Obviously not all hernias can be repaired in an MIS approach, and these data are likely reserved for small- to medium-sized hernias.

Tsereteli et al. compared 134 patients with BMI >40 kg/m^2 with 767 patients with BMI <40 kg/m^2 undergoing laparoscopic intraperitoneal onlay mesh (IPOM) and found fewer hernia recurrences (8.3% in morbidly obese and 2.9% in nonmorbidly obese) but no difference in the rate of complications.[18] However, it is important to highlight that hernia defects were not closed in these patients, which can affect hernia recurrence, particularly in obese patients.

Laparoscopic and robotic retromuscular repairs, such as the extended totally extraperitoneal (eTEP) approach, has also been reported in obese patients. In one of the most extensive series of MIS retromuscular repairs, Addo et al. evaluated 461 patients with BMI >35 kg/m^2 and BMI <35 kg/m^2 and found no differences in hernia recurrence or complications.[19] This highlights that MIS can affect outcomes in obese patients and may play an important role when enrolling patients and balancing the risks and benefits of preoperative optimization programs.

Medical Nonpharmacologic Weight Loss Programs

In the previously discussed RCT, Bernardi et al. found no differences in the percentage of hernia-free and complication-free patients undergoing a prehabilitation program with access and training information versus standard counseling.[8] However, it is important to highlight that only 22% of patients in the prehabilitation group met the 7% total body weight loss goal,[7] highlighting the limitations of prehabilitation programs that do not offer supervised training activities or pharmacologic or surgical weight loss interventions. One observational study with 191 hernia patients reported a mean weight loss of 6 kg in patients who participated in a weight loss program compared with 1.8 kg in patients who did not enroll.[20] One of the most relevant findings of this study is that 55% of patients enrolled in a prehabilitation program were lost to follow-up and only 9 out of 80 patients (11%) enrolled in a program met the weight loss goal and underwent hernia repair.[20] These studies highlight how challenging it is to successfully implement such programs because patient engagement is poor and few patients meet their weight loss goals.

A small retrospective study by Rosen et al. evaluated the effect of a multidisciplinary approach with a low-calorie diet (<800 kcal/day) and protein-sparing fast (1.2–1.5 g/kg/day of protein according to ideal body weight) supervised by weight loss specialists in 25 patients with BMI greater than 35 kg/m^2.[21] The average duration of the preoperative program was 17 months, and patients lost approximately 18% of their initial weight and a mean BMI decrease of 9 points. Interestingly, 88% of patients could maintain their weight loss at 18-month follow-up postoperatively.[21] The protein-sparing fast supervised by a weight loss specialist appears to be a valuable strategy for medical weight loss.

Medical Pharmacologic Weight Loss

Several medications are approved for pharmacologic weight loss. However, the data on preoperative use of these medications are lacking, and no studies include patients undergoing abdominal wall surgery. A small nonrandomized study evaluated the use of phentermine-topiramate for 3 months preoperatively and postoperatively in patients with BMI >50 kg/m^2 undergoing laparoscopic sleeve gastrectomy (LSG).[22] Patients with adjunct weight loss medication lost two times more weight preoperatively than patients undergoing LSG only. The postoperative weight loss at 12- and 24-month follow-up was also greater in the phentermine-topiramate group.[22]

The current, most effective pharmacologic group for medical weight loss is the glucagon-like peptide-1 (GLP-1) agonists. Several RCTs with different GLP-1 agents have reported substantial and sustained reductions in body weight compared with placebo. In an RCT of patients including 338 patients, GLP-1 agonist use was associated with up to 24.2% mean weight reduction after 48 weeks.[23] Unfortunately, there is a lack of studies examining the preoperative use of GLP-1 agonists in the literature. Pharmacologic medical weight loss can be associated with significant side effects and requires a specialized follow-up program, which is better suited for primary care physicians and weight management specialists with experience with these medications. Further studies are needed to evaluate the role of these agents in the preoperative optimization of patients undergoing abdominal wall surgery.

Metabolic and Bariatric Surgery

Despite bariatric surgery being more effective than nonsurgical weight loss in multiple RCTs, there is still no consensus on the exact role of neoadjuvant bariatric surgery in preoperative optimization. Although surgical weight loss is highly effective, not all patients are appropriate candidates for metabolic surgery. These procedures can also result in unique complications and malnutrition that can potentially affect outcomes. At the same time, the weight loss provided by these interventions can increase abdominal wall compliance, reduce wound complications, reduce recurrence rates, and provide better control of comorbidities like diabetes.

Morrell et al. evaluated 20 patients who underwent LSG with complex ventral hernias, and 16 subsequentially underwent VHR on average 22.6 months after the first visit to the abdominal wall surgeon clinic.[24] Two patients required reoperation related to the LSG: one laparoscopic reexploration for bleeding and another required laparoscopic resleeving because of retained fundus and stalled weight loss. A 22.2% average decrease in BMI was noted, and two patients sustained hernia-related complications while waiting for an elective operation; both developed small bowel obstruction in which one required an emergent operation. No recurrences were seen on average follow-up of 20.9 months.[24]

In another case series of complex abdominal wall hernias that underwent neoadjuvant metabolic surgery, Schroeder et al. evaluated 12 patients (6 LSG, 6 laparoscopic Roux-en-Y gastric bypass [LRNYGB]) and reported no reoperations or complications.[25] The average excess BMI loss was 64.6%, and the mean BMI at hernia repair was 33 kg/m^2 versus 48 kg/m^2. The average time to undergo hernia repair was 22.3 months, and two patients were repaired emergently: one for strangulation and another for obstruction. Two patients developed superficial SSIs treated with antibiotics only, and no recurrences were noted on the mean follow-up of 21.9 months.[25]

Several studies have also described performing VHR simultaneously as laparoscopic bariatric surgery, especially for smaller defects. An analysis of 988 patients with concomitant VHR using the NSQIP database and propensity score matching found that patients with simultaneous VHR had higher 30-day morbidity, including reoperations and readmissions.[26] Chan et al. also reported synchronous VHR and bariatric surgery in 45 patients with placement of coated polypropylene or polytetrafluoroethylene mesh, with no recurrences noted at median follow-up of 13 months. However, two (4.4%) patients developed mesh infection that required drainage and antibiotics without mesh removal, and one patient required diagnostic laparoscopy for drainage of intraabdominal abscess.[27] We recommend caution with using intraperitoneal coated meshes in the setting of contamination because of higher rates of mesh infection and lower rates of mesh salvage with intraperitoneal meshes.[28]

Studies have also compared performing staged VHR with synchronous VHR before or during LSG. In a retrospective study with propensity score matching, 6.7% recurrence was noted in the staged group and 24% in the concurrent surgery group at a median 4.6-year follow-up.[29] BMI at hernia repair was 34.1 kg/m^2 after a mean of 21.5 months in the bariatric-first group and 42.4 kg/m^2 in the synchronous group. Most patients in both groups had hernias size >7 cm, and most patients underwent open retromuscular repair with mesh.[29] A retrospective study with propensity score matching evaluating patients with small (<4 cm) umbilical hernias compared patients with simultaneous LSG or VHR after weight loss after LSG and found similar rates of recurrence and complications in both groups.[30] Patients who underwent simultaneous VHR and LSG had a mean BMI of 42.7 kg/m^2, and patients with delayed repair achieved a mean BMI of 31 kg/m^2 approximately 13.7 months after LSG.[30]

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) published detailed recommendations on the management of obese patients with hernias.[31] In their guidelines, a staged approach is recommended when possible. Still, some patients might require concomitant repair because of hernia anatomic location, history of recent small bowel obstruction, or need to reduce the bowel from the hernia sac for an anastomotic procedure in patients for whom LSG is not appropriate. In cases where concomitant hernia repair is reasonable, the authors recommend primary closure for smaller hernias and bridged repair with biologic or bioresorbable meshes as a temporizing measure for medium to large hernias. Empty hernia defects >10 cm may also be left alone, as the risk of incarceration is theoretically lower. Regarding the timing of hernia repair after bariatric surgery, SAGES recommends waiting until the nadir weight loss is achieved. However, it is reasonable to perform VHR in symptomatic patients who continue to lose weight despite BMI <35 kg/m^2 and in patients whose nadir weight continues to exceed the ideal BMI for hernia repair despite multiple weight loss interventions.[31]

Recommendations

We encourage preoperative weight loss in obese patients because it can promote overall health and potentially improve outcomes, particularly in complex hernias. It is essential to acknowledge that achieving meaningful weight loss can be extremely challenging and may require a significant number of resources to establish successful medical weight loss programs, require more invasive interventions such as neoadjuvant bariatric surgery, and take a substantial amount of time to achieve a weight loss goal before hernia repair, which can expose these patients to the risk of an emergent hernia operation.

We believe that strict BMI or weight loss cutoffs are not beneficial. The decision to proceed with surgery in obese patients should be individualized because some patients may never achieve significant weight loss or have significant symptoms that would benefit from earlier hernia repair. Additionally, we recommend MIS approaches when feasible, and if an open approach is required, we would avoid procedures that require undermining of large areas of skin and soft tissue. We use a medical weight loss program for 3 to 6 months in most obese patients and refer them to our metabolic institute, which includes medical and surgical weight loss. However, if significant symptoms are present or weight loss is not achieved despite multiple interventions within this period, VHR should be considered with appropriate risk-benefit discussions with the patients.

NUTRITIONAL SUPPLEMENTATION

Introduction

Poor nutritional status has been described as one of the leading risk factors for postoperative morbidity. Still, there is a lack of evidence supporting preoperative nutritional optimization, especially in patients undergoing abdominal wall surgery.

Nutritional Status Assessment

Several nutritional markers and nutritional scores can be valuable adjuncts in assessing nutritional risk preoperatively. In one study using the NSQIP database with 65,192 patients, serum albumin <3.5 g/dL was associated with an increased risk of major complications, mortality, and readmissions. Complications were decreased with each 0.1 g/dL increase in albumin levels.[32] Although albumin levels are one of the most used nutritional markers, hypoalbuminemia can occur in patients with chronic inflammation and has a relatively long half-life (approximately 3 weeks), limiting the applicability of using albumin alone for nutritional assessment in the preoperative setting. Prealbumin is another serum marker that can be more useful to assess short-term nutrition because it has a short half-life of approximately 3 days. However, prealbumin is also an acute phase reactant, and its level can be inaccurate in patients with ongoing inflammatory status. Adding C-reactive protein (CRP) levels can help assess inflammatory status and understand how it can interfere with nutritional serum markers. We believe that an increasing ratio of prealbumin and albumin associated with decreased levels of CRP can be a helpful sign of improved nutrition and a positive nitrogen balance.

In addition to laboratory and anthropometric values to assess nutrition, preoperative imaging can be a helpful adjunct. As patients undergoing abdominal wall surgery often have preoperative CT scans, this can add valuable information regarding nutritional status and provide accurate prognostic information. Although fat distribution in preoperative CT has been shown to correlate with postoperative outcomes, Schlosser et al. found that sarcopenia and psoas muscle size on CT was not associated with adverse outcomes in patients undergoing open VHRs.[15,33]

Obtaining volumetric data from CT scans may require computer skills, which can be highly user dependent, and specialized software that can perform such measurements. Using an image-based deep learning model, artificial intelligence can predict abdominal wall reconstruction complexity and postoperative infection, outperforming expert surgeons.[34] Further development of this technology will enhance preoperative planning and improve surgical risk discussion with patients.

Nutritional Supplementation

Although most patients undergoing abdominal wall surgery are not severely malnourished, patients with extensive comorbidities and complex hernias, such as enterocutaneous fistulas, can present in a catabolic state and potentially benefit from preoperative nutritional interventions. Patients should maintain at least a normocaloric diet with a protein intake of 1.2 g/kg, associated with dietary consultation and oral nutritional supplementation (ONS), if appropriate.[35]

The enteral route should always be preferred, but in some cases of patients who are malnourished or at severe nutritional risk and unable to meet energy requirements by the enteral route, parenteral nutrition (PN) should be considered.

Immunonutrition

In addition to addressing malnutrition, immunonutrition (IN) is another consideration preoperatively, as surgery can induce several metabolic alterations leading to increased catabolism and an inflammatory state. Immune-enhanced diets (IEDs) include arginine, glutamine, omega-3 fatty acids, and nucleotides. Several basic science studies have shown that these nutrients can reduce proinflammatory proteins and counteract stress-induced decreases in T-cell cytokine production and antigen-presenting cell activity.[36,37] Supplementing these preoperatively theoretically can overcome the deficiency that can occur after the stress response from surgery.

A large meta-analysis containing 83 RCTs evaluating IN in patients undergoing abdominal surgery found that although a benefit was seen with IED, considering all trials, these effects disappeared when excluding trials at high or unclear risk of bias. The authors also noted that industry-founded trials were more likely to report positive effect in overall complications.[38] In another meta-analysis containing only RCTs comparing IEDs with regular ONS, no differences were seen in outcomes, suggesting that ONS is an acceptable alternative to IN, especially because ONS contains elements used in IN like arginine, omega-3, and other nutrients like proteins, minerals, and vitamins.[39]

In abdominal wall surgery, there is a lack of studies evaluating IN. In a small RCT of 40 patients undergoing enterocutaneous fistula takedown, patients in the intervention group were preoperatively administered arginine and glutamine supplementation for 7 days. Patients who underwent immune supplementation had lower interleukin-6 (IL-6) and CRP levels and also fewer infectious complications and fistula recurrence.[40] Although this trial provides positive results with IN in abdominal wall surgery, the number of patients was small, limiting the applicability of their findings.

Recommendations

A combination of anthropometric measurements, laboratory values, and CT volumetric analysis can be used to assess preoperative nutritional status. In malnourished patients, we recommend a normocaloric and high-protein diet with ONS if appropriate. PN is reserved for patients unable to tolerate EN. No high-quality evidence supports IN in patients undergoing abdominal surgeries; our approach is to selectively offer ONS or IEDs for 5 to 7 days to highly motivated patients.

MANAGEMENT OF DIABETES MELLITUS

A considerable body of evidence exists regarding the negative effect of uncontrolled diabetes mellitus (DM) in both basic science and clinical outcomes after cardiac, orthopedic, and general surgery.[41–43] However, despite being one of the most challenging concerns of public health, the management of diabetes remains poorly studied in the field of hernia repair.

Pathophysiology

The wound-healing process is complex and depends on numerous molecular pathways, which are modulated in the presence of DM. In vivo studies looking at impaired wound healing in the presence of DM have found a modulated local and systemic response to injury in the presence of DM because of impaired growth factor expression, severely impaired angiogenesis during the various stages of wound healing, increased production and release of pro-inflammatory cytokines, impaired function of macrophages and stem cells, and diminished apoptosis.

Outcomes

Glycemic control is typically assessed by measuring HbA1c. This value represents the percentage of glycosylated hemoglobin, which spans the lifetime of the erythrocyte. This is a test of choice because it reflects glycemic control over approximately 3 months.[44] A large systematic review and meta-analysis looked at the impact of glycemic control on outcomes in cardiac surgery by reviewing

30 studies including 30,000 patients.[41] In this study, low preoperative HbA1c ($<7.5\%$) was associated with a lower risk of sternal wound infections when compared with patients with HbA1c $>7.5\%$ (risk ratio 0.50; 95% CI 0.32–0.80; $p = 0.003$). In addition, both early and late mortality improved with better glycemic control. Hernia-specific data are sparse. The European Hernia Society conducted a systematic review to evaluate patient prehabilitation before VHR. With regard to DM, only five publications were considered for analysis.[45] Four of these studies were retrospective reviews that reported increased risk for SSOs and hernia recurrence in diabetic patients. The other study was another expert consensus statement based on systematic reviews.[46] However, the data gathered were not from hernia-specific studies and showed increased odds of 1.69 to 5.8 for postoperative complications when HbA1c was $>6.0\%$ to 7.0%. A more recent retrospective review of prospectively collected data on the hernia-specific ACHQC database looked at the association of HbA1c and outcomes of VHRs in diabetic patients.[47] The patients were divided into two groups (HbA1c $<8\%$ and HbA1c $\geq 8\%$). After analyzing over 2000 patients, this study found no clinically significant differences in the rates of wound complications, reoperations, readmissions, length of stay, or mortality.

Recommendations

Poorly controlled diabetes has been shown to have a negative impact on wound morbidity in several types of surgeries. These results are often extrapolated into the field of hernia surgery, so the consensus has been to avoid elective hernia repair in patients with HbA1c $>8\%$. However, as more hernia-specific studies are being presented, this notion is being challenged. At this time, we recommend that all diabetic patients should have their HbA1c checked before surgery. For those with HbA1c $>8\%$, the surgeon must determine whether it is the result of poor compliance or lack of medical access. A referral to endocrinology is preferred for those with poorly controlled diabetes, and the surgeon should emphasize the importance of glycemic control on the patient's overall health. Currently, there is no evidence to recommend delaying hernia repair until the HbA1c is lowered to some arbitrary cutoff. Finally, DM, especially type 2, may be associated with morbid obesity. Referral to either medical or surgical weight loss before elective hernia repair may be beneficial in this select group of patients.

MANAGEMENT OF SMOKING

Worldwide, it is estimated that 33% of adult males and 7% of adult females are active smokers despite growing evidence that smoking is a leading cause of death.[48] Similar to the negative impact of poorly controlled diabetes, there is no shortage of studies highlighting the risk of smoking in patients undergoing surgical procedures in several surgical specialties such as gastrointestinal, orthopedic, and urology.[49–52] However, recent data have challenged this perceived increased risk in smokers undergoing hernia repair.

Pathophysiology

The detrimental effects of smoking on overall health are ubiquitous. These include reduced ability to heal wounds, immunosuppression, susceptibility to infections, increased risk of cardiovascular disease, and decreased respiratory function.[51] Regarding wound healing, smoking releases reactive oxygen species, producing a proinflammatory state and impairing wound proliferation and remodeling.[53] More specifically, smoking increases the overall neutrophil cell count by as much as 20%, which in turn leads to the release of proinflammatory substrates such as tumor necrosis factor (TNF)-α, IL-1, IL-8, and granulocyte-macrophage colony-stimulation factor from alveolar macrophages.[54] In addition, smoking has been shown to inhibit fibroblast chemotaxis, migration, and proliferation as well as reduced collagen I and III production.

OUTCOMES

In the context of VHR, there have been several large-pool registry studies demonstrating that smoking increases the risk for wound infection. An NSQIP review by DeLancey et al. analyzing 220,000 ventral and inguinal hernias showed that smokers had increased risk for wound infection: superficial: OR 1.34 (95% CI 1.22–1.48); deep: OR 1.31 (95% CI 1.11–1.54); organ space: OR 1.45 (95% CI 1.17–1.79); and dehiscence: OR 1.41 (95% CI 1.11–1.80). However, the actual percentage differences of any wound complication were much smaller: 2.58% in current smokers and 1.69% in nonsmokers.[55] Analyzing patients in the ACHQC, Petro et al. compared current smokers with never-smokers and found similar rates of SSI (4.1% vs. 4.1%, $p = 0.98$), SSOs requiring procedural intervention (SSOPI) (6.2% vs. 5.0%, $p = 0.43$), reoperation (1.9% vs. 1.2%, $p = 0.39$), and all 30-day morbidity (7.5 vs. 6.6, $p = 0.60$). Smokers had higher rates of SSOs (12.0% vs. 7.4%, $p = 0\ .03$), which was driven by increased seromas.[56] In their retrospective propensity score matching analysis, Kudsi et al. reported comparable results when looking at clinical outcomes of robotic VHR between smokers and nonsmokers. SSOs and infections were similar when comparing smokers to nonsmokers (7.6% vs. 5.4%, $p = 0.472$; 5 vs. 0, $p = 0.060$, respectively).[53]

Recommendations

The large body of evidence implicating smoking in postoperative complications certainly outnumbers the results in hernia-specific populations. Importantly, the most cited large data pools lack the granularity of hernia-specific techniques and often produce statistically significant results that may not be clinically relevant. When considering the body of evidence against smoking and the negative effects on general health, all surgeons should encourage smoking cessation before any operative procedures. Preoperative counseling should be provided, and appropriate referrals should be made for those motivated to quit smoking. However, the surgeon should be truthful when presenting the data to smokers being evaluated for hernia repair. Historically, the authors viewed smoking as a contraindication to hernia repair. Currently, we continue to encourage patients to quit smoking. However, we will now proceed with surgery even if the patient has failed to quit, understating that for Centers for Disease Control and Prevention (CDC) class I hernia repairs there is an increased risk of SSOs, but the majority of these do not require further intervention. Importantly, a prerequisite for such a drastic change in practice is outcomes tracking. The surgeon must be aware of their current clinical outcomes and should be able to track any signals once a change in practice is implemented.

IMMUNOSUPPRESSION

Immunosuppression represents a unique set of challenges in the context of hernia repair, as a significant portion of this cohort are solid organ transplant patients who rely on these medications to prevent rejection. These challenging groups of patients are thought to be at increased risk for developing wound complications and hernia recurrence because of their immunosuppressed state.

Pathophysiology

The most common classes of immunosuppressive drugs encountered by the hernia surgeon include calcineurin inhibitors (cyclosporine and tacrolimus), antimetabolites (azathioprine and mycophenolate mofetil), mammalian target of rapamycin (mTOR) inhibitors (sirolimus or everolimus), TNF inhibitors, and steroids. Cyclosporine is a cyclical peptide that binds to intracellular cyclophilin, and together they act to inhibit calcineurin.[57] This results in the inhibition of T-cell proliferation and differentiation. Tacrolimus also blocks calcineurin by binding to the FK506-binding proteins (FKBPs) in a mechanism like cyclosporine. Azathioprine and mycophenolate mofetil inhibit purine synthesis, reducing B and T cells. Sirolimus and everolimus, like tacrolimus, bind to FKBP but affect the signal transduction pathway by blocking the activity of mTOR. This affects the phosphatidylinositol-3 kinase-Akt signaling pathway, which is an important checkpoint for cell growth and proliferation as well as proinflammatory factors IL-2, IL-15, and vascular endothelial growth factor, which are critical for wound healing. TNF is a central component of the inflammatory response. It is activated by macrophages, which, in turn, activate several signaling pathways including mitogen-activated protein (MAP) kinase, caspases, and nuclear factor-kB. These pathways lead to increase expression of other inflammatory cells (B and T cells), inflammatory cytokines (IL-1, IL-6), cell adhesion molecules, matrix metalloproteinase, and inducers of apoptosis.

Outcomes

A large registry-based study looked at the effect of immunosuppression, including corticosteroid treatment, on the outcomes of inguinal hernia repair in over 2000 patients.[58] When looking at immunosuppression (yes vs. no), there were no significant differences in SSIs (0.65% vs. 0.70%, $p = 1.000$) or seromas (1.22% vs. 1.57%, $p = 0.382$). Another study looked at the risk factors for hernia recurrence, SSO, and those requiring procedural intervention in 166 patients who underwent incisional hernia repair after abdominal transplantation.[59] Interestingly, immunosuppression had a lower risk of SSO and SSOPI (OR 0.33, 95% CI 0.11–1.00, $p = 0.05$; OR 0.14, 95% CI 0.02–0.88, $p = 0.036$). Finally, Kushner et al. looked at wound morbidity in immunosuppressed patients undergoing open or robotic bilateral transversus abdominis release.[60] Of the 321 patients included in the study, 20% were on chronic immunosuppression. When looking at chronic immunosuppression (yes vs. no), there were no significant differences in SSO (20.6% vs. 21.3%, $p = 0.92$), SSI (14.3% vs. 10.8%, $p = 0.50$), SSOPI (3.2% vs. 5.4%, $p = 0.48$), or readmission for wound-related compilations (1.6% vs. 4.3%, $p = 0.33$). Inhibitors of mTOR deserve special attention. Both animal and human studies have shown a significant decrease in wound strength and delayed healing.[57] As for the inhibitors of TNF, a large multicenter prospective cohort study of 947 patients studied the use of this class of medication and the risk for postoperative infectious complications in patients undergoing surgery for irritable bowel disease (IBD).[61] The rates of any infection (18.1% vs. 20.2%, $p = 0.469$) and SSI (12.0% vs. 12.6%, $p = 0.889$) were similar for patients currently exposed to TNF inhibitors when compared with the unexposed, respectively.

Recommendations

In general, calcineurin inhibitors and antimetabolites should be continued in the perioperative period. Trough levels of calcineurin inhibitors should be monitored daily to determine the appropriate dosage and ensure appropriate maintenance therapy levels. If elective surgery is planned, mTOR inhibitors should be stopped 4 to 6 weeks before surgery in consultation with the patient's transplant team. Currently, there is not enough evidence to suggest stopping TNF inhibitors before surgery. Patients on chronic steroids may require stress doses depending on the length of therapy and drug dosage at home. Finally, immunosuppressed patients, especially transplant patients, require a multidisciplinary team effort, including the transplant team and pharmacy.

PREOPERATIVE ADJUNCTS FOR VENTRAL HERNIA REPAIR

A critical component for the successful treatment of ventral hernias is closure of the midline. However, for complex hernias, this may not always be possible. Incomplete fascial closure, also referred to as a *bridged repair,* has been associated with increased SSI and recurrence rates. Component separation techniques were developed as effective means to close complex defects. However, even with advancements made with these techniques, loss-of-domain hernias often have chronic muscle retraction, reducing the compliance of the abdominal wall, which, in turn, hinders the reduction of hernia contents inside the abdomen and subsequently fascial closure. Three main preoperative adjuncts have been developed to facilitate fascial closure in complex hernias: botulinum toxin A (BTA), soft tissue expanders, and progressive preoperative pneumoperitoneum (PPP).

Pathophysiology

BTA is a neurotoxin that is produced by the bacterium *Clostridium botulinum*. This toxin, typically injected under ultrasound guidance, blocks the release of the neurotransmitter acetylcholine, resulting in temporary muscle paralysis. With regard to hernia repair, BTA is thought to cause relaxation and elongation of the lateral abdominal wall musculature (external oblique, internal oblique, and transversus abdominis muscles), which are thought to increase abdominal wall compliance and facilitate fascial closure.[62] PPP, first used in 1947, is a technique where the intraabdominal cavity is filled with, most commonly, ambient air via an intraperitoneal catheter. The volume of gas is gradually increased until a predetermined volume is reached or the patient can no longer tolerate it. The theorized effects of this technique, which acts as a pneumatic soft tissue expander, include elongation of soft tissues, improvement in respiratory capacity, and tension-free abdominal closure.[63] Soft tissue expanders are implants placed subcutaneously, between the internal and external obliques, posterior rectus sheath, or intramuscularly. After a period of 1 to 6 months, the expansion of the implants is started and continued until adequate soft tissue is recruited. This may result in the mobilization of abdominal wall fascia and soft tissue to allow for reconstruction.[64]

Outcomes

Although the use of these preoperative adjuncts is increasing, data that objectively justify clinical benefits are lacking and consist of mostly retrospective reviews. A retrospective propensity-scored matched study looked at patients who underwent abdominal wall reconstruction with (75 patients) and without BTA (145 patients).

Patients with BTA had higher fascial closure rates (92% vs. 81%, $p = 0.036$).[65] A subsequent study by the same group showed no difference in fascial closure rates when BTA and preperitoneal mesh placement were compared with component separation alone (100% vs. 90.5%, $p = 0.11$, respectively).[62] A different propensity-scored matched study looked at the ACHQC registry and compared the fascial closure rate with and without BTA use.[66] There was no difference in fascial closure rates between treatments with and without BTA (86% vs. 85.2%, $p = 0.934$, respectively). Regarding PPP, a systematic review and meta-analysis looked at 53 articles for a total of 1216 patients. In this study, the pooled data showed 86% fascial closure rates; however, there was no comparison arm. Of note, the authors found a 12% rate of complications associated with this procedure. Although the majority were minor (abdominal pain, subcutaneous emphysema, and dyspnea), there were two hollow viscus perforations and five deaths thought to be related to PPP.[67] Finally, tissue expansion data are even more lacking when compared with BTA and PPP. Tissue expansion is mainly used when there is inadequate soft tissue coverage, and a systematic review of 14 studies including 103 patients highlighted the feasibility of this technique.[68] However, the authors also highlighted the potential for complications during the expansion phase, which included wound infection ($n = 11$), hematoma ($n = 8$), and rupture of the implant ($n = 3$). After the reconstruction, the main complications included recurrence ($n = 12$), skin necrosis ($n = 6$), and mortality ($n = 2$).

Recommendations

It is important to highlight that the use of BTA is off-label when injected into the lateral abdominal wall musculature. The US Food and Drug Administration (FDA) requires the botulinum toxin manufacturers to include a black box warning about the possible risks associated with the systemic spread of the toxin, including death. To date, there is no high-quality objective evidence that BTA, which adds significant cost to the hernia repair, aids with fascial closure. At this time, the use of BTA in abdominal wall reconstruction should be limited to uses in a trial context. Tissue expanders and PPP can be valuable when there is inadequate soft tissue coverage, so these procedures should be in the surgeon's armamentarium. A multidisciplinary effort should be made when employing this technique, including providers who have experience with tissue expanders.

PREHOSPITAL SCRUB

Preoperative showering with an antiseptic agent such as chlorhexidine gluconate (CHG) has been a well-accepted practice among many surgical specialties to reduce the skin flora. However, it is not clear that this practice results in fewer SSIs.

Pathophysiology

Chlorhexidine has both bacteriostatic and bactericidal properties. It is a positively charged molecule that is attracted to the negatively charged bacterial cell wall, forming strong adsorption of phosphate-containing molecules.[69] This is followed by penetration through the bacterial cell wall, damaging its integrity and resulting in outflow of cytoplasmic components such as potassium, limiting the function of enzymes associated with the cytoplasmic membrane. Finally, CHG causes cytoplasmic coagulation and precipitation by forming complexes with phosphorylated molecules such as nucleic acids and adenosine triphosphate.

Outcomes

When looking to give recommendations for the use of CHG, the World Health Organization (WHO) conducted a systematic review to assess the effectiveness of CHG when compared with plain soap. Nine studies including more than 17,000 adult patients investigated preoperative bathing or showering with an antimicrobial soap compared with plain soap and found that bathing with CHG soap does not significantly reduce SSI rates compared with bathing with plain soap (OR 0.92; 95% CI: 0.80–1.04). Specific to hernia surgery, Prabhu et al. analyzed 3924 patients, and multivariate logistic regression modeling showed that the CHG scrub group had a higher incidence of SSOs (OR 1.34; 95% CI 1.11–1.61) and SSIs (OR 1.46; 95% CI 1.03–2.07) when compared with the no CHG group.[70] After these results, some of the study's authors stopped using prehospital CHG as part of the quality improvement initiative. They looked at the data 4 years after this change, and when 4276 patients were analyzed, the rates of SSO, SSIs, and SSOPIs at 30 days were similar before and after prehospital CHG discontinuation.[71]

RECOMMENDATIONS

In their global guidelines for preventing SSI, the WHO recommends that it is good clinical practice for patients to bathe or shower before surgery with a plain or antimicrobial soap. Currently, there is no evidence to recommend the use of prehospital CHG to reduce the rate of wound infections after hernia repair.

SUMMARY

In this chapter we described the current evidence on preoperative optimization of the patient with a hernia and provided several evidence-based recommendations as follows:

1. Preoperative optimization strategies can be a valuable opportunity to motivate patients to improve general health and minimize the impact of modifiable risk factors on postoperative outcomes.
2. The current evidence behind preoperative optimization in hernia repair is limited and likely overemphasized by current guidelines. Further high-quality studies are needed before making strong recommendations that have significantly affected patients undergoing abdominal wall surgery.
3. It is important to acknowledge that, most of the time, a significant amount of effort and time is required for patients to achieve meaningful weight loss. These patients are subject to the risk of undergoing an emergency operation that is associated with worse outcomes than in an elective setting.
4. We strongly discourage the use of cutoffs to select patients for operative interventions. We recommend the use of a patient-centered approach based on the patient's symptoms, baseline comorbidities, preoperative risk assessment, and surgical approach to determine the need and length of preoperative optimization in comorbid patients.
5. Patients with multiple modifiable risk factors likely benefit more from preoperative optimization strategies than patients with isolated risk factors.
6. A multidisciplinary effort is paramount to establishing optimal preoperative optimization strategies to promote a greater impact on postoperative outcomes.
7. There is no evidence to recommend delaying hernia repair until the HbA1c is lowered to an arbitrary cutoff.

8. Continue to encourage patients to quit smoking. However, the surgeon may proceed with surgery even if the patient has failed to quit depending on the complexity of the case and technique used.
9. For elective surgeries, mTOR inhibitors should be stopped 4 to 6 weeks before surgery in consultation with the patient's transplant team.
10. The use of BTA in abdominal wall reconstruction should be used in a trial context, and tissue expanders and PPP can be valuable adjuncts for achieving soft tissue coverage.

This study evaluated the impact of HbA1c in patient undergoing ventral hernia repair using the Abdominal Core Health Quality Collaborative database. The patients were divided into two groups HbA1c <8% and HbA1c >8%. There was no association between HbA1c and operative outcomes in diabetic patients undergoing elective ventral hernia repair.

Alzatari R, Hassanein R, Doble J, Huang LC, Poulose BK. Determining the impact of individual ventral hernia repair complications on patient-reported quality of life. *Hernia*. 2023;27:687-694.

This study performed a propensity score matched analysis using the Abdominal Core Health Quality Collaborative comparing HerQLes scores at 1-year following ventral hernia repair in patients that had complications or no complications. The study found that developing wound complications had a significant negative impact in quality of life at 1 year in patients undergoing ventral hernia repair.

Bernardi K, Olavarria OA, Dhanani NH, et al. Two-year outcomes of prehabilitation among obese patients with ventral hernias. *Ann Surg*. 2022;275:288-294.

This is a 2-year follow-up study of a blinded randomized control trial evaluating the impact of prehabilitation in obese patients seeking ventral hernia repair. There were no differences in 2-year outcomes in obese patients who underwent prehabilitation versus standard care.

Horne CM, Augenstein V, Malcher F, et al. Understanding the benefits of botulinum toxin A: retrospective analysis of the Abdominal Core Health Quality Collaborative. *Br J Surg*. 2021;108:112-114.

This study evaluated the role of chemical component separation utilizing botulinum toxin A in patients with large ventral hernias using the Abdominal Core Health Quality Collaborative. This study did not demonstrate improved fascial closure rates, decreased need for component separation or improved patient reported outcomes with the use of botulinum toxin A.

Petro CC, Haskins IN, Tastaldi L, et al. Does active smoking really matter before ventral hernia repair? An AHSQC analysis. *Surgery*. 2019;165:406-411.

This study evaluated patients undergoing elective clean open ventral hernia repair using the Abdominal Core Health Quality Collaborative. Current smokers were propensity matched to patients who never smoked. There was increased rates of surgical site occurrences, wound cellulitis and seromas with smoking, but no differences in surgical site infections, surgical site occurrences requiring procedural intervention, reoperations and overall 30-day morbidity.

INTRODUCTION AND ANATOMY

A ventral hernia (VH) is an anatomic defect of the anterior abdominal wall leading to herniation of preperitoneal or intraperitoneal contents and is seen as a bulge by the patient. VHs can be categorized as spontaneous or acquired. Examples of spontaneous VHs include umbilical hernias and epigastric hernias. The majority of acquired VHs are the result of surgical incisions, referred to as *incisional hernias.* It is estimated that 12% of major open abdominal surgical incisions and 3% of major minimally invasive operation incisions will develop an incisional hernia. The greatest risk of development occurs in the first 5 years. Traumatic hernias are also a type of acquired VH. Although not considered a true hernia (given the absence of a fascial defect and hernia sac), *diastasis recti* refers to progressive stretching of the linea alba leading to separation of the rectus abdominis muscles and manifests as a midline bulge that is frequently confused for a hernia.

Ventral hernia repair (VHR) of both spontaneous and acquired hernias remains one of the most common surgical procedures performed by general surgeons. A recent study demonstrated that in the United States, rates of VHR increased to over 600,000 between 2006 and 2016.[1] In recent decades, the landscape of VHR has evolved dramatically with the advent of many new materials to reinforce the abdominal wall and several new surgical techniques, including minimally invasive approaches. Despite these advances, hernia recurrence rates after VHR remain high, up to 40% in some studies.[2] This observation demonstrates that there is still significant room for improvement in hernia repair outcomes and that no single silver bullet exists against VH. Surgeons must maintain a broad armamentarium to provide tailored approaches to hernia patients. The goal of VHR should be to durably repair and restore abdominal wall anatomy with the lowest possible rate of complications.

A clear understanding of abdominal wall anatomy, including musculoaponeurotic structures, blood supply, and innervation, is imperative for the surgeon performing VHRs. The anterior abdominal wall is a hexagonal area defined superiorly by the costal margin and xiphoid process; laterally by the midaxillary line; and inferiorly by the symphysis pubis, pubic tubercle, inguinal ligament, anterior superior iliac spine (ASIS), and iliac crest. Layers of the anterior abdominal wall from anterior to posterior include skin, subcutaneous tissue, superficial fascia, deep fascia, muscle, transversalis fascia, preperitoneal fat and areolar tissue, and peritoneum. The superficial fascia of the abdominal wall is composed of both Camper's and Scarpa's fascia fused into a single layer above the umbilicus. Below the umbilicus, the division between a fatty outer anterior layer, Camper's fascia, and a membranous inner layer, Scarpa's fascia, becomes apparent. Camper's fascia is continuous with the superficial adipose tissue and may vary in thickness depending on patient body habitus. It extends inferiorly with the superficial thigh fascia and extends inferiorly to the scrotum in males and labia majora in females.

The anterior abdominal wall is formed mainly by rectus abdominis muscles and their associated fascia. The rectus abdominis muscles are covered by anterior and posterior fascia, the anterior and posterior rectus sheath. Fusion of bilateral rectus abdominis fascia in the midline forms the linea alba, which extends from the xiphoid process to the pubic symphysis. This critical structure is typically more well defined above the umbilicus. The lateral abdominal wall is formed by the external oblique, internal oblique, and transversus abdominis muscles, each with its own associated fascia. Their insertion to the lateral edge of the rectus abdominis forms the linea semilunaris.

The arcuate line is located midway between the umbilicus and symphysis pubis and is the anatomic point where the posterior rectus sheath transitions from being a fusion of the posterior fascial layer (or lamella) of the internal oblique and transversus abdominis aponeuroses cranially to being the transversalis fascia and parietal peritoneum only caudally. Above the arcuate line, the anterior rectus sheath is formed by contributions of the external oblique and the anterior lamella of the internal oblique aponeuroses. Below the arcuate line, the anterior rectus sheath is composed of the external oblique, internal oblique, and transversus abdominis aponeuroses, leaving the transversalis fascia and peritoneum posteriorly (Fig. 80.1).

The lateral abdominal muscles are the external oblique, internal oblique, and transversus abdominis. The external oblique originates from the lower eight ribs, courses in an inferomedial orientation (often referred as *hands in pockets*), and inserts into the pubic crest. Its fascia forms the inguinal ligament, which extends from the ASIS to the pubis. The internal oblique muscles originate from the thoracolumbar fascia, the anterior two-thirds of the iliac crest, and the lateral portion of the inguinal ligament. The muscle fibers course in a superomedial direction (opposite to the external oblique) and insert into the inferoposterior borders of the 10th to 12th ribs superiorly and into the pubic crest inferiorly. The transversus abdominis muscles are the deepest of the lateral abdominal wall. They originate from the anterior three-fourths of the iliac crest, the lateral third of the inguinal ligament, and the inner surface of the lower six costal cartilages, where they interlock with fibers of the diaphragm. The origin is muscular but transitions into a broad flat aponeurosis medially and fuses with the posterior layer of the internal oblique fascia before inserting into linea alba. Below the arcuate line, the condensation of the transversus abdominis and internal oblique aponeuroses forms the

conjoint tendon, which inserts into the pubic crest. Importantly, the transversus abdominis extends medially to the linea semilunaris and contributes to the posterior rectus sheath. The muscle fibers of the transversus abdominis muscle are more medial in the upper abdomen and become more lateral in the lower abdomen.

The blood supply to the abdominal wall is divided into three zones as described by Huger et al.[3] Zone I includes the upper- and mid central abdomen and is supplied by the superior epigastric artery (SEA) and the deep inferior epigastric artery (DIEA). Zone 2 includes the midline and lateral lower abdominal wall and is supplied by the epigastric arcade, superficial inferior epigastric, superficial external pudendal, and superficial circumflex iliac arteries. Zone 3 includes the lateral abdominal wall and is supplied by the musculophrenic, lower intercostal, and lumbar arteries (Fig. 80.2).

Both the SEA and DIEA lie on the posterior aspect of the rectus muscles and supply the rectus abdominis, subcutaneous tissue, and skin through musculocutaneous perforators. The two branching vascular systems converge within the rectus abdominis muscle at a point between the xiphoid process and the umbilicus.

The blood supply to the lateral abdominal wall includes the musculophrenic artery, deep circumflex iliac artery, and branches of the lower intercostal and lumbar arteries. These vessel arcades course within the plane between the transversus abdominis and internal oblique muscles (Fig. 80.3).

Motor and sensory innervation of the abdominal wall originates from branches of the intercostal nerves (T7–L1). Motor innervation is supplied by the nerve roots from T7–T12 intercostals and iliohypogastric and ilioinguinal nerves. These nerve roots travel perpendicularly in the lateral abdominal wall in between the transversus abdominis and the internal oblique muscle (the transversus abdominis plane) and pierce the posterior rectus sheath at the level of the linea semilunaris. After entering the posterior rectus sheath, the neurovascular bundles segmentally innervate the rectus abdominis muscle. Intraoperative identification and preservation of the neurovascular bundles are critical to maintain rectus abdominis trophism and avoid inadvertent injuries to the linea semilunaris.

MANAGEMENT OF VENTRAL HERNIAS

Diagnosis

A thorough history and physical examination should be performed. When interviewing the patient, risk factors for hernia development, symptoms, and effects on quality of life should be investigated. Surgical history is critical to obtain, particularly in the setting of recurrence. If the patient has had a history of hernia repair, details on mesh placement and type (if used) and whether a complex approach had been attempted in the past, such as component separation, should be elicited. Operative reports should be sought and obtained if possible because they can provide invaluable information for operative planning. Any past abdominal wall imaging should be reviewed. On physical examination, it is critical to note all past surgical incisions. The patient should also be examined both standing and supine. When standing, any abdominal wall asymmetry should be documented. When supine, the patient should be asked to perform a Valsalva maneuver and a straight bilateral leg raise to assess for fascial defects and the extent of abdominal wall weakness (e.g., diastasis recti). Unusual or complex presentations of hernias require CT imaging. For clinical documentation purposes, the most accepted classification is the one developed by the European Hernia Society (Figs. 80.4 and 80.5).[4]

Open Approaches to Ventral Hernia Repair

The first reports of open hernia repair date back to the 4th century BCE and possibly even earlier.[5] Although modern hernia surgery employs a multitude of novel approaches and technology, the basic tenant of a hernia repair remains the same: durable reapproximation of healthy fascial tissue to prevent re-herniation of intraabdominal contents. Hernia repairs should attempt to restore native anatomy and distribute tensive forces over the area where the hernia formed.[6,7] The following section describes the various approaches and techniques for open VHR.

Primary Repair

A *primary repair* refers to suture closure of a fascial defect without the use of a mesh prosthesis. This technique is often used in patients with small, primary fascial defects such as umbilical or epigastric hernias <2 cm.[8–10] In general, primary repair should be avoided for incisional hernias, given a significantly higher recurrence rate compared with repair using mesh. However, sometimes primary repair is used in settings of contamination or in emergent cases when implantation of mesh may be ill-advised. Primary repairs should only be used in appropriately selected patients as it is well established that mesh reduces the rate of hernia recurrence. In a randomized controlled trial (RCT), umbilical hernias <4 cm in maximum diameter demonstrated significantly less recurrence when mesh was used (4% vs. 12%, hazard ratio [HR] = 0.31, 95% confidence interval [CI] 0.12–0.80).[11] With smaller hernias (1–2 cm), the absolute risk reduction from mesh use becomes more modest (2% vs. 8%, HR = 0.23, 95% CI 0.05–1.07) compared with larger (2- to 4-cm) defects (9% vs. 22%, HR = 0.39, 95% CI 0.12–1.30).[11]

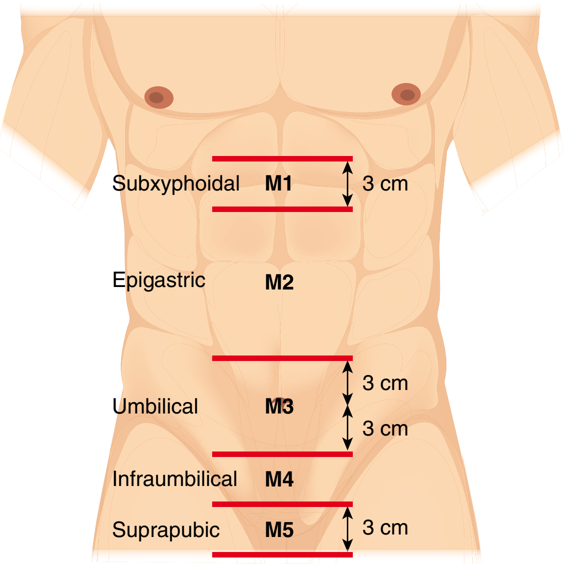

FIGURE 80.4 European Hernia Society midline hernia classification. (From Muysoms FE, Miserez M, Berrevoet F, et al. Classification of primary and incisional abdominal wall hernias. *Hernia*. 2009;13[4]:407-414.)

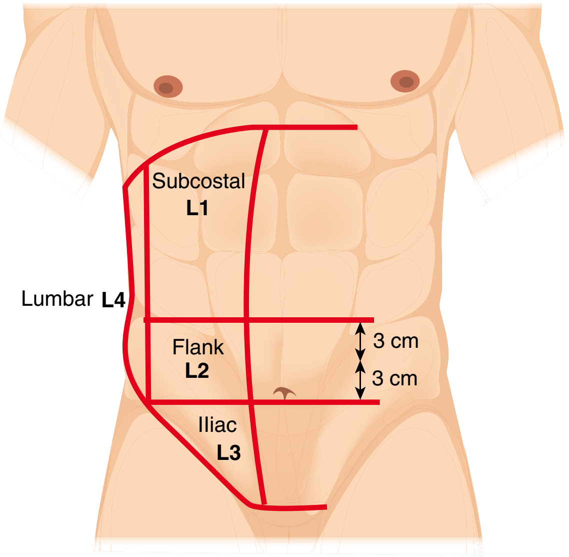

FIGURE 80.5 European Hernia Society lateral hernia classification. (From Muysoms FE, Miserez M, Berrevoet F, et al. Classification of primary and incisional abdominal wall hernias. *Hernia*. 2009;13[4]:407-414.)

Advocates of primary repair argue that avoidance of mesh implantation and its associated complications is worth the modest increase in recurrence of smaller defects. Guidelines differ in size cutoffs for recommending primary versus mesh repair, with some recommending the use of mesh in hernias >1 cm and others for hernias >2 cm.[6,7] Data extrapolated from the STITCH trial suggest that a small bites approach (0.5-cm × 0.5-cm bites) with a 4:1 ratio of suture to incision length using slowly absorbable suture minimizes the risk of hernia during laparotomy.[12] This approach is often applied to hernia repair. When deciding on an approach to small primary hernias, it is important to discuss the expected outcomes and absolute risk reduction with the use of mesh. Patients may desire to forego mesh placement and accept a higher risk of recurrence.

Fascial healing is a complex process that can take over a year to complete. Between the eighth postoperative day and second month, there is a rapid increase in fascial strength to about 50% of its original strength. This time frame corresponds to the beginning of the proliferative phase of wound healing to the end of collagen synthesis.[13] This time frame also suggests that at least a slowly absorbable suture material should be selected. A rapidly absorbing suture would otherwise risk failure before the expected significant regain in fascial strength. Although some select permanent suture for fascial closure in hernia repair, the authors typically do not choose this suture for fascial closure because it may lead to foreign body sensation and suture granulomas.

Before the introduction of mesh in the 1960s, multiple different techniques for the primary closure were described using both absorbable and nonabsorbable suture materials. The modified Mayo technique involves overlapping the edges of the fascia, creating fascial redundancy with two separate suture lines in an interrupted fashion, also colloquially referred to as *pants over vest.*[14] The "keel" repair used the dissected hernia sac to create redundancy posteriorly with anterior rectus sheath relaxing incisions to take tension off the midline repair. Steel wire repairs were used with reportedly good effect, but difficulty in replications of these results and application of the technique led to its disuse.[15] Currently, modern evidence for open primary repair is increasingly sparse, largely because of its abandonment in favor of mesh repair.

Mesh Repair

The introduction of mesh in the 1960s significantly reduced hernia recurrence rates, and mesh technology continues to evolve to this day.[11,16] Meshes can be classified as either permanent or absorbable. Permanent meshes are typically made from synthetic polymers, such as polypropylene, polyester, or polytetrafluoroethylene (PTFE), which will resist degradation by the patient's immune response. These synthetic meshes are typically used for definitive VHR and abdominal wall reconstruction. Each mesh varies in weight (g/cm^2), porosity, and hydrophilicity and may feature a composite design with an antiadhesive barrier. It is important to note that mesh weight should only be compared between meshes made from the same material. Ultra-lightweight polypropylene and lightweight polyester meshes have been shown to have increased central mesh failure.[16] Macroporous lightweight polypropylene mesh has demonstrated higher rates of bacterial clearance compared with other weights and porosities.[17] When synthetic mesh is placed in an intraperitoneal position, it must either be a composite mesh with an antiadhesive barrier or made of expanded polytetrafluoroethylene (ePTFE), which resists tissue incorporation. In the event of infection, composite meshes, especially PTFE, often require removal.

Absorbable meshes can be categorized into biologic and biosynthetic types. Biologic meshes are composed of acellular collagen matrices derived from either animal or human tissue and are gradually degraded by the host's biologic processes. Biologic meshes are classified based on their source material (including species and tissue type), postharvest processing techniques (e.g., cross-linked vs. non–cross-linked), and sterilization methods (e.g., gamma radiation, ethylene oxide gas sterilization, or nonsterilized). They are often preferred in contaminated cases, where permanent mesh is typically contraindicated due to the higher risk of infection. However, the use of biologic mesh has fallen out of favor recently because of high associated recurrence rates and costs.[18] Biosynthetic meshes are constructed from synthetic materials that absorb over time, such as polyglactin in Vicryl Mesh (Ethicon, Inc., Somerville, NJ). Polyglactin is rapidly absorbable and hydrolyzes completely in 2 to 3 months. These absorbable meshes are often used in contaminated fields where fascial closure is desired but the use of permanent synthetic mesh is prohibited. Other materials include poly-4-hydroxybutyrate (P4HB), which is found in Phasix Mesh (BD, Franklin Lakes, NJ) and is degraded over 12 and 18 months, and polyglycolide-trimethylene carbonate copolymer, which is found in GORE BIO-A Tissue Reinforcement (W.L. Gore & Associates, Inc., Newark, DE) and is degraded in about 6 months.[19,20] Further studies are necessary to better ascertain the optimal use for these materials. Mesh can be placed in several different locations, each with its own risks and benefits (Fig. 80.6).

Intraperitoneal underlay repair. *Intraperitoneal,* or "underlay," *mesh* refers to a mesh placed deep to the parietal peritoneum. Mesh placed in this position must be coated with an antiadhesion barrier or be absorbable to allow for direct contact with the bowel. Underlay mesh can be placed minimally invasively (most common) or via an open approach with the use of transfascial fixation sutures.

To perform this technique with an open approach, a midline incision is made. The hernia contents are completely reduced. Adhesions to the anterior abdominal wall are taken down circumferentially around the fascial defect to allow for adequate mesh overlap. The hernia defect is measured to determine mesh size. Correctly sizing the mesh is technically challenging in these cases because the mesh must be placed when the incision is open and lie flat when the fascia is closed. An oversized mesh will wrinkle with defect closure, whereas an undersized mesh will be prone to failure. Although wide overlap (>4–5 cm) is often advocated in laparoscopic underlay approaches, studies have not consistently shown that degree of mesh overlap is a significant predictor of recurrence in open procedures.[21] The authors still recommend aiming for a 5-cm mesh overlap in open procedures. Skin flaps are created by dissecting the subcutaneous tissue away from the anterior rectus fascia to facilitate the placement of transfascial sutures. The mesh is then secured circumferentially with these sutures, which are passed through the abdominal wall and along the mesh's edge. After all sutures are placed, the mesh is parachuted into position and tied down above the fascia. It is important to measure the location of the transfascial sutures to prevent wrinkling of the mesh when closing the hernia defect. The anterior rectus sheath is closed with a slowly absorbable suture. If large skin flaps are created, subcutaneous drain placement should be considered to prevent seroma formation.

Proponents of open underlay techniques argue that the mesh's placement provides a mechanical advantage against outward

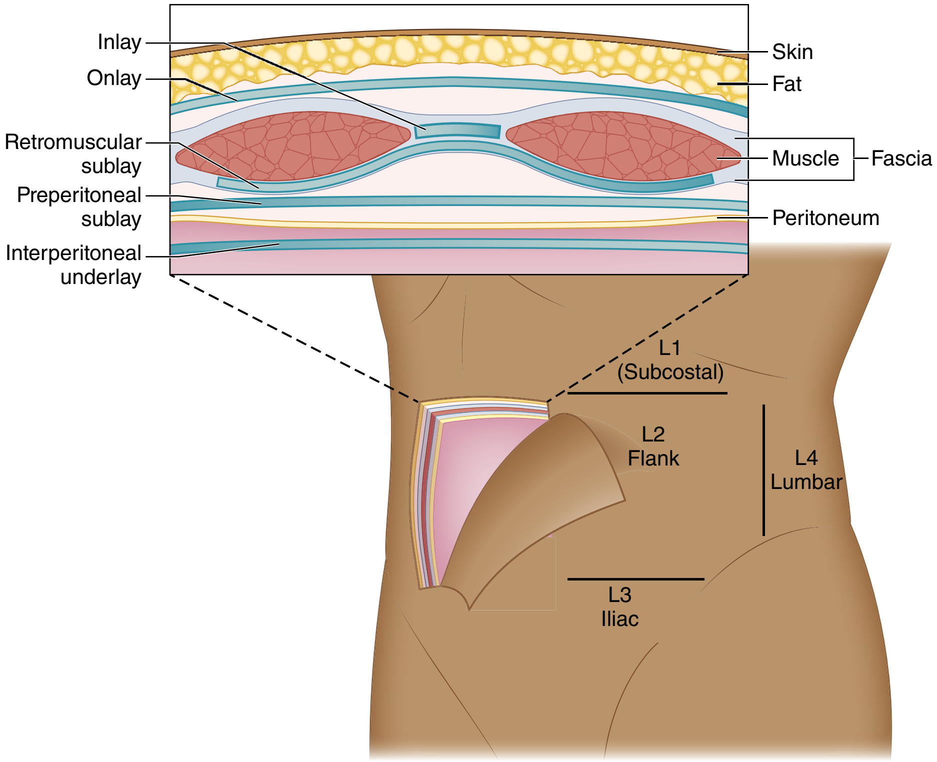

FIGURE 80.6 Mesh positions for ventral hernia repair. (Courtesy Board of Regents at the University of Texas System.)

intraabdominal pressure. Additionally, positioning the mesh away from the skin reduces the risk of contamination and lowers the likelihood of superficial surgical site infections (SSIs). Although underlay mesh placement is still commonly used in minimally invasive approaches, the rise of sublay techniques (see next section) has largely replaced open underlay approaches. Recent meta-analyses have shown sublay techniques to be superior in both recurrence and SSI rates compared with underlay techniques.[22]

Retromuscular sublay repair. Mesh placed in the retrorectus position is also known as a *retromuscular sublay,* or "Rives-Stoppa," repair. This technique of opening the posterior rectus sheath and placing mesh in the retrorectus space was described contemporarily by Rives in 1985[23] and later Stoppa in 1987.[24] This technique places the mesh deep to the rectus muscle and superficial to posterior sheath, parietal peritoneum, and sometimes hernia sac. This technique offers two key advantages: The mesh is placed outside the peritoneum, so a coated mesh is not needed, and it provides a highly vascularized area that supports better mesh integration.

This procedure is carried out by performing a laparotomy, reducing any herniated viscera, and lysing any anterior abdominal wall adhesions. The hernia sac should be carefully preserved because it can sometimes be needed later for closure of the posterior layer. On each side, the rectus muscle is identified, and the posterior sheath is opened at its medial attachment to the linea alba. It is critical not to cause an iatrogenic injury to the linea alba. The hernia sac should be left attached to the posterior sheath if possible. The posterior rectus sheath incisions are carried cranially and caudally. The retrorectus space is then developed laterally toward the semilunar line, where the neurovascular bundles of the rectus muscles are encountered (as shown in Fig. 80.3) and protected. The extent of dissection depends on the size of the fascial defect and area necessary for mesh overlap, but it should be carried at least 5 cm superior and inferior to the defect. Superiorly, this dissection can extend past the costal margin and xiphoid process to the central tendon of the diaphragm. Inferiorly, the dissection can be carried below the pelvic brim into the space of Retzius. In most cases, surgeons will attempt to achieve at least 5 cm of mesh overlap from the hernia defect. However, the size of the cavity is largely determined by the anatomic constraints of the retrorectus space, and mesh is usually sized to occupy the entire extent of this space. A transversus abdominis release (TAR) allows for development of the retrorectus space beyond the linea semilunaris. The TAR technique will be described later in the chapter. Any holes in the posterior sheath are closed using absorbable suture. The posterior rectus sheath and hernia sac (if needed) are closed using a running, absorbable suture. The mesh is trimmed to the size of the retrorectus space and positioned flat against the posterior layer. Mesh fixation is not needed but can be performed based on surgeon preference.[25] Some options for mesh fixation include interrupted sutures, transfascial fixation, and fibrin sealant. In our practice, mesh fixation is typically not used. The anterior rectus fascia is then closed using slowly absorbable suture.

Sublay mesh placement has been shown to be superior to both onlay and underlay mesh in terms of SSI and recurrence rates.[22,26] In a meta-analysis of mesh location in open VHR, sublay mesh placement was associated with significantly lower recurrence rates and SSI rates compared with onlay, inlay (bridge), and underlay mesh placement. These results have led to a significant shift toward sublay mesh placement when doing open procedures. Open "Rives-Stoppa" repairs have improved over the years, with recent studies showing recurrence rates ranging from 7% to 11%.[25–28]

Preperitoneal sublay repair. In addition to the retrorectus plane, *sublay mesh* may also refer to mesh placed in the preperitoneal plane. The benefit of the preperitoneal plane is that it is not bound by the semilunar line like the retrorectus plane. In addition, a preperitoneal approach is less anatomically altering than a retrorectus repair because no fascial layers are incised. Preperitoneal repairs have gained popularity, with excellent results in expert hands. Heniford et al. have demonstrated excellent results even in large and complex hernias.[29] However, a preperitoneal dissection can be technically challenging to perform because the peritoneum can be extremely thin and difficult to dissect.

The procedure begins similarly to other open VHRs with a laparotomy, reduction of hernia contents, and lysis of adhesions. The preperitoneal space is entered and developed laterally, inferiorly, and superiorly to the fascial defect. The hernia sac should be protected and left in continuity with the preperitoneal flap because it can be used to facilitate closure of the flap later. The preperitoneal plane is dissected to allow for at least 5 cm of mesh overlap circumferentially. Once an adequate flap has been dissected, the space is measured, and a mesh is cut to size. Any holes in the peritoneal flap should be closed with absorbable suture. The hernia sac can be used to patch holes or facilitate closure of the flap if needed. The peritoneal flap is then closed with running absorbable suture. Mesh is placed in the preperitoneal space with optional fixation. The anterior rectus fascia is closed with running, slowly absorbable suture.

Bridging/Inlay repair. A bridging repair (inlay) is used when the fascial edges of a hernia defect cannot be closed primarily, and a mesh prosthesis must be used to bridge the gap between fascial edges. After a midline incision, the hernia contents are reduced, and adhesions to the anterior abdominal wall are lysed. The anterior rectus sheath should be cleared 1 cm circumferentially so that it can be clearly identified. The fascia is closed, starting from both the superior and inferior ends of the incision. The fascia is closed as much as possible from both ends. When it is no longer possible to close the fascia without undue tension, a mesh is sewn to the fascial edges using running suture.

This technique is often employed in the setting of extremely large defects where fascial approximation cannot be achieved. It is also used in some reoperative hernia surgeries where advanced techniques and tissue planes have already been used, in the emergency setting, after treatment of pathologies such as abdominal compartment syndrome (ACS), or with massive traumatic tissue loss.

Bridging mesh techniques are wrought with poor outcomes. Bridged repair has the highest recurrence rate among any of the mesh locations. It also leads to the poorest functional results because the linea alba (or fascial continuity in nonmidline hernias) is not restored. Although this technique is at times necessary in patients with massive hernias, every effort should be made to reoppose the fascia. Despite this, large retrospective studies have shown that although bridging repair is associated with a high degree of patient-perceived bulge, it does demonstrate quality-of-life benefits compared with preoperative patient-reported scores.[30] In addition, such a repair is sometimes the only option.

Onlay repair. Mesh that is placed anterior to the anterior rectus sheath is considered an onlay repair. After hernia sac reduction, the anterior rectus sheath edges are cleared so that they are clearly identifiable. The fascia is closed using running, slowly absorbable suture. Skin flaps are developed between the anterior rectus fascia and the subcutaneous tissue circumferentially to allow for wide mesh overlap (at least 5 cm). The mesh is secured in place using either interrupted or running suture directly between the mesh and the fascia. Care must be taken to sew the mesh to the fascia and not to the subcutaneous tissue to prevent migration, and dissecting skin flaps in the appropriate plane will ensure this. Subcutaneous tissue and skin are closed over the mesh per surgeon preference.

Onlay mesh has the advantage of keeping mesh out of the abdominal cavity and may be a valuable tool for patients at high risk for laparotomies as a result of dense adhesions or inability to tolerate prolonged operative times for a complex repair. However, it is associated with high rates of surgical site occurrences (SSOs), infections, and hernia recurrence.

Component Separation

Component separation refers to the creation of myofascial advancement flaps to assist with medialization of the rectus muscle and primary fascial closure. *Component separation* can refer to the division of either the external oblique muscles (anterior component separation) or transversus abdominus muscles (posterior component separation). These techniques are most often employed when the linea alba cannot be reapproximated because of the size of the hernia defect.

External oblique release (anterior component separation). Anterior component separation was initially described in 1990 by Ramirez and colleagues. It involves the division of the external oblique fascia and musculature. The amount of release it provides is debatable but is approximately 3 to 10 cm per side.[31]

The open anterior component separation begins with laparotomy, reduction of hernia contents, and lysis of adhesions to the anterior abdominal wall. Subcutaneous flaps are developed between the anterior rectus fascia and subcutaneous fat. The flaps are extended laterally to the linea semilunaris. The aponeurosis of the external oblique is incised 2 cm lateral to the semilunar line, and the external oblique muscle fibers are completely divided. This division is extended superiorly over the rib and inferiorly to the inguinal ligament. The space between the divided external and internal oblique muscle is developed. In addition, the posterior rectus sheath is incised and opened along the edge of the linea alba. This maneuver allows for medialization of the rectus muscles and closure of larger defects. The repair can then be performed with the surgeon's preferred mesh location. Finally, drains are placed in subcutaneous space.

The large skin flaps required for this procedure are associated with significant wound complications. As such, modifications to this procedure have been developed, including periumbilical perforator–sparing techniques, oblique release through separate incisions, and endoscopic release. A periumbilical perforator–sparing anterior component separation is performed similarly to a traditional open anterior component separation, but the periumbilical perforators, which lie in a 3-cm radius around the umbilicus, are preserved. Another approach is to use separate incisions to perform the release. Rather than creating skin flaps, small incisions are made along the semilunar line. The external oblique is divided as far cranially and caudally as possible through each incision, and a new incision is made once the limit is reached. Finally, with an endoscopic component separation, a small incision is made in the upper or lower quadrant at the semilunar line, and a balloon dissector is used to create a vertical tunnel in the subcutaneous space.[32] Two additional trocars are placed under direct vision. The external oblique is identified and divided using electrocautery from the costal margin to the inguinal ligament.

The initial use of the anterior component separation technique helped improve recurrence rates of large ventral incisional hernias from 50% down to 4.2% to 10% for large hernias.[33,34] The anterior component separation has been a mainstay in the armamentarium of abdominal reconstruction surgeons for many years and continues to be employed with good results. However, it has fallen out of favor with many hernia surgeons because of a high rate of wound complications and the development of the posterior component separation.

Transversus abdominis release (posterior component separation). Developed by Novitsky and colleagues in 2012, the TAR has quickly become a key instrument in abdominal wall reconstruction. The procedure allows for up to 8 cm of medialization depending on technique, avoids SSI complications from large skin flaps, allows for wide retromuscular sublay mesh placement, and can be performed via minimally invasive approaches.[35]

The anatomic considerations of the Rives-Stoppa and preperitoneal repair techniques, along with the mechanical theory of the anterior component separation, evolved into the development of the posterior component separation technique. The procedure is performed as a continuation of the Rives-Stoppa retrorectus dissection and can provide mesh overlap beyond the constraint of the linea semilunaris, and it offers increased fascial medialization. After development of the retrorectus space to the linea semilunaris as marked by the neurovascular bundles, the posterior lamellae of the internal oblique and underlying transverse abdominis muscle fibers are divided medially to the linea semilunaris. Once the muscle fibers are completely divided, the underlying transversalis fascia and/or peritoneum is visualized. This dissection is extended cranially and caudally, extending from under the diaphragm superiorly to the arcuate line inferiorly. The release can be started using either a "top-down" or "bottom-up" approach. The top-down approach involves beginning the TAR at the superior portion of the muscle and carrying it down toward the arcuate line. The muscle fibers of the transversus abdominis are more medial superiorly and thus more easily identifiable in this area. The transverse abdominis becomes more aponeurotic inferiorly. With the bottom-up approach, the arcuate line is identified. The posterior lamellae of the internal oblique aponeurosis and the underlying transverse abdominis (typically the aponeurotic portion) are divided medially to the linea semilunaris, beginning from the arcuate line up to the costal margin. Once the transverse abdominis is completely divided, the retromuscular space is developed laterally. Bare muscle can be seen superficial to the flap and confirms the true retromuscular or pretransversalis plane. If bare muscle fibers are not seen, the posterior layer is likely solely the peritoneum. Although it is safe to be in either the preperitoneal or pretransversalis plane, the surgeon must be able to identify which plane they are in throughout the operation. No muscle should be left of the posterior layer. Otherwise, the dissection has occurred in the incorrect plane. In addition, care should be taken to leave the muscular fibers of the diaphragm up when the superior dissection is performed because otherwise, an iatrogenic Morgagni hernia may occur. The retromuscular space is typically developed until the posterior layer lies flush with the intraabdominal viscera. The posterior layer is closed with running slowly absorbable suture. Mesh is placed in the retromuscular sublay plane with wide overlap to the full extent of the dissected retromuscular space. Mesh can be fixated with transfascial sutures to Cooper's ligament/pubis and to the costal margin if desired; however, fixation is optional. Although data are limited, drains are often placed in the transversus abdominus plane to control potential seroma or hematoma formation, which may impede mesh integration.

This technique has demonstrated excellent results, with recurrence rates under 5%.[34,36,37] The TAR is limited by the requirement for access to the retrorectus plane and may be complicated by previous repairs, transfascial sutures, previous stomas, transperitoneal tacks, or denervation of the rectus muscle resulting from previous surgery through chevron or Kocher incisions. Additionally, performing a TAR after an anterior component release is controversial due to the risk of abdominal wall destabilization, particularly along the linea semilunaris, when posterior component separation follows a previous anterior component separation.

Minimally Invasive Approaches to Ventral Hernia Repair

Minimally invasive approaches are permeating all aspects of surgery, including hernia repair and abdominal wall reconstruction. Although the general steps of each operation remain the same, the minimally invasive surgery (MIS) approach requires specific knowledge relating to positioning, instrumentation, and possible complications.

A key aspect of MIS is trocar placement and selection. The surgeon must place ports such that they are triangulating the area of interest. Increasing use of robotic surgery has made port placement more forgiving because there is less ergonomic strain with certain angles. Radially expanding blunt-tip trocars are often used because they are less traumatic and reduce port site bleeding. Upsizing of the trocar for mesh deployment may be necessary to prevent damage to the mesh. As with open cases, mesh contact with skin should be avoided to decrease contamination with skin flora.

Similar to open hernia repair, some cases may require extensive adhesiolysis. Accidental enterotomy or serotomy can occur. Based on the experience of the surgeon and whether contamination is limited, the injury may be addressed with MIS and the hernia repair performed immediately.[38] However, conversion to laparotomy should be considered if the extent of injury and contamination cannot be addressed in a minimally invasive fashion. After bowel injury repair, the surgeon may choose to delay hernia repair after a period of observation and parenteral antibiotics.

In addition to reducing the hernia, closure of the defect before placing mesh results in fewer instances of recurrence, bulging, and seroma (Fig. 80.7). The general benefits seen with MIS, such as decreased wound complications, are applicable to VHR and abdominal wall reconstruction.[39]

Intraperitoneal Underlay Repair

Minimally invasive intraperitoneal underlay mesh repair (IPUM) was the first minimally invasive VH technique described by LeBlanc et al. in 1992.[40] It is now a widespread technique because of its relatively technical simplicity and shorter learning curve while offering benefits of MIS, such as diminished SSI and length of stay.[41] Similar to the open approach, the MIS IPUM approach involves placing the mesh intraperitoneally. The location of the mesh is classically referred to as *underlay* because it is under the peritoneum and secured to the abdominal wall.

There are several options for port size and placement. MIS surgeons often opt for a triangulation approach and will place the ports along the side of the patient that increases surgeon mobility by decreasing the physical limitations of the patient's legs or chest. Of note, care should be taken not to place ports through the linea semilunaris because this may increase the risk of port site hernias. The herniated contents are then reduced, and the posterior fascia

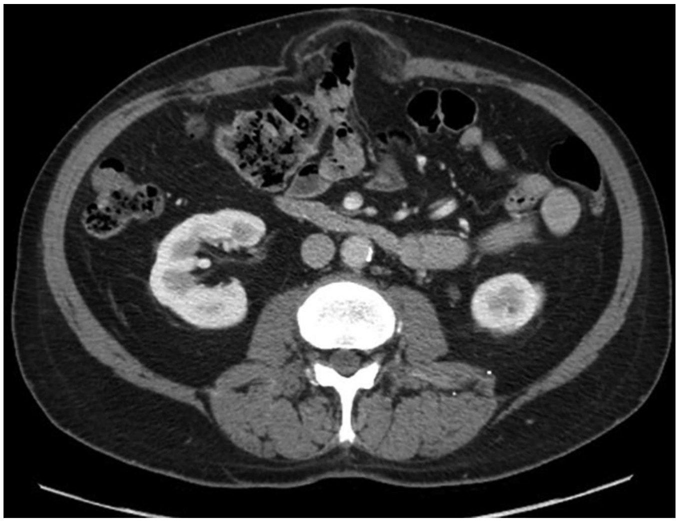

FIGURE 80.7 Abdominal CT scan after intraperitoneal underlay mesh repair without defect closure. The mesh has conformed to the defect, resulting in bulging and eventration of mesh.

should be cleared of any adipose tissue to encourage good apposition of mesh to fascia. Closure of the hernia defect is preferred because it decreases the rate of pseudorecurrence, which occurs when the mesh is secured at its periphery but bulges through the original defect like a trampoline. Wide defects that are unable to be approximated may not be the best suited for IPUM, and a more advanced technique may be necessary.

Two common options for mesh fixation in this approach are tacks or transfascial sutures, both of which have been associated with increased postoperative pain. The mesh is in direct contact with the underlying intraperitoneal viscera, and a composite mesh with an antiadhesive barrier should be selected. Intraperitoneal mesh can potentially lead to adhesions and bowel erosion with fistula development. Despite a wide array of composite meshes and other innovations, there has yet to be a proven barrier developed against these issues. Furthermore, when using 10-mm ports to insert the mesh, care must be taken to close the port site to decrease the risk of port site hernias. Refer to Video 80.1 for further details.

Transabdominal Preperitoneal Repair

More recently, the MIS transabdominal preperitoneal (TAPP) repair has gained popularity to address the limitations of the MIS IPUM approach, such as intraperitoneal mesh and the necessity of using a coated mesh. The port placement and importance of defect closure are analogous to the IPUM technique. This is a versatile technique because of the extent to which the preperitoneal space can be developed. However, preperitoneal dissection can be challenging due to the thin nature of the peritoneum and prior surgeries that may have violated the peritoneum.

A rule of thumb is to place the camera port about 15 cm away from the hernia. This allows 5 cm of mesh overlap, 5 cm for adequate peritoneal flap coverage of the mesh, and an additional 5 cm to visualize the initiation of the flap. After port placement, the herniated contents are reduced. An incision is made in the peritoneum, and the preperitoneal space is developed. As the surgeon begins the procedure, they must correctly identify the plane that lies between the peritoneum and the posterior rectus sheath, lateral to the hernia defect. Once the plane is dissected on either side of the hernia, the surgeon can then reduce any preperitoneal adipose tissue. The dissection continues in that plane beyond the hernia to provide a sufficiently large peritoneal flap to cover the entire mesh. The hernia defect is then closed with absorbable barbed suture, such as V-Loc (Medtronic, Minneapolis, MN) or Stratafix (Ethicon, Raritan, NJ), and an uncoated synthetic mesh is secured to the abdominal wall with interrupted sutures. The peritoneal flap is then closed with absorbable barbed suture, with care to close any other fenestrations in the peritoneum that may have been made. If the peritoneal flap cannot be dissected or there is an excessive amount of peritoneal defects, the surgeon may convert to another approach, such as IPUM or retromuscular repair. Refer to Video 80.2 for further details.

Subcutaneous Onlay Repair

In 2018, Claus et al. reported the subcutaneous onlay laparoscopic approach (SCOLA).[42] This is an anterior minimally invasive approach that can simultaneously repair diastasis and midline hernias. Traditionally, diastasis was addressed by plastic surgeons through transverse lower abdominal incision, plication, and removal of excess skin. SCOLA offers a novel MIS approach, particularly useful for patients who do not require dermolipectomy.

The technique begins by placing the three ports along the Pfannenstiel incision line. If done laparoscopically, the midline suprapubic port will be 11 mm, and the lateral ports will be 5 mm.

When inserting the port, the dissection stops at the anterior aponeurosis of the rectus abdominis muscle. Pressure in this space can reach up to 10 mm Hg, and the surgeon can dissect the tissue from the aponeurosis toward the xiphoid cranially and the ribs laterally (Fig. 80.8).

The umbilical stalk is typically transected and re-created later during closure. Once this is accomplished, the hernia sac can be opened and the content reduced. With the use of a running barbed suture, the hernia defect can be closed and any diastasis recti plicated. As with other hernias, the use of a polypropylene mesh, here placed in an onlay position, reduces the risk of recurrence. Various methods can be used to keep this mesh in place, such as glue, sutures, or tacks. A drain is left in typically left in place.

Complications associated with this technique are mainly seroma formation but also include recurrences and wound infections. Of note, the patient population chosen for SCOLA repair had small hernias (<4 cm) and diastasis (<4 cm). The initial series has shown some positive results, and SCOLA may be appropriate in carefully selected patients. Refer to Video 80.3 for further details.

Retrorectus Sublay Repair

Larger (4- to 8-cm) midline hernias or hernias associated with a diastasis may benefit from the Rives-Stoppa repair.[43] The MIS Rives-Stoppa repair follows the same general steps as an open approach as described earlier in the chapter. Although the pertinent anatomy for an open retromuscular repair is the same for an MIS approach, there are stark differences in the operative approach and setup. Whereas open approaches typically begin with a midline incision to gain exposure, a minimally invasive approach has many incisional options. The location of the hernia and anatomic constraints, such as rectus abdominis width and bony prominences, will dictate the ideal location for initial port placement. Furthermore, a retromuscular repair may be performed using either a transabdominal or extraperitoneal approach, depending on patient factors. The patient is typically positioned supine in a flexed position with the arms tucked to increase mobility around

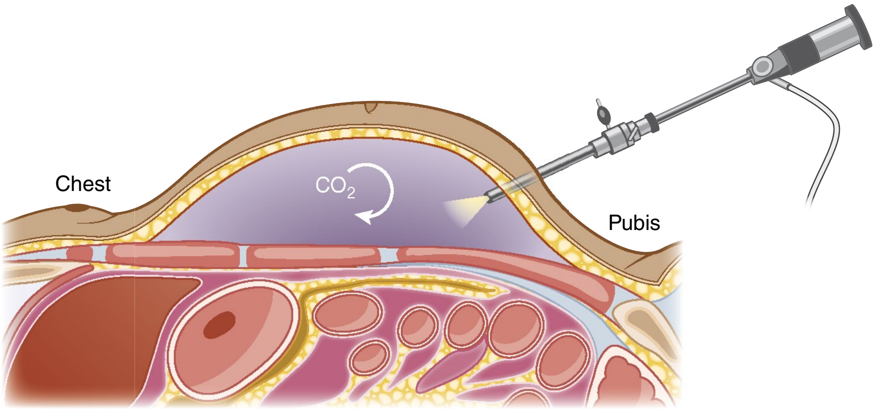

FIGURE 80.8 Insufflation of subcutaneous space during subcutaneous onlay laparoscopic approach. (From Claus CMP, Malcher F, Cavazzola LT, et al. Subcutaneous onlay laparoscopic approach [SCOLA] for ventral hernia and rectus abdominis diastasis repair: technical description and initial results. *Arquivos Brasileiros de Cirurgia Digestiva*. 2018;31[4].)

the patient. Flexion of the patient allows the chest and thighs to drop slightly away from the operative field to increase the operative working room of the surgeon and prevent robotic arm collision. Examples of robotic port placement are shown later; however, the same principles apply to traditional laparoscopy, such as triangulation of the working ports and the target. A retrorectus repair is limited laterally by the linea semilunaris. If further retromuscular space is required for hernia management, a TAR will be necessary.

A transabdominal retromuscular approach begins with establishment of pneumoperitoneum and placement of intraperitoneal ports. The retrorectus space is entered by incising the medial attachment of the posterior rectus sheath, and the retrorectus space is developed. Opposing ports are placed if necessary, and the contralateral retrorectus space is developed. The hernia defect is approximated with absorbable barbed suture, and plication of the linea alba is performed if necessary. An uncoated mesh is placed within the retromuscular space, and the posterior layer is closed. Although bridging peritoneum may suffice, it is our practice to approximate the posterior rectus sheaths if there is not excessive tension. It is critical to ensure any defects in the posterior layer are addressed to prevent intraparietal hernias.

The enhanced or extended totally extraperitoneal (eTEP) approach for retromuscular repair begins with direct access to the retrorectus space. The eTEP approach relies on the "crossover maneuver," which uses the midline preperitoneal space to bridge the bilateral retrorectus spaces.[44] Thus, a relative contraindication to this approach is a xiphopubic incision that may have significantly disrupted the midline preperitoneal space. In these cases, a transabdominal approach is preferred. Preoperative imaging is critical in determining if there is a safe plane for crossover. The authors prefer optical entry with advancement of the port through the rectus muscle and stopping just superficial to the posterior rectus sheath. The retrorectus space is then developed until other working ports can be placed.

Once the interface of the posterior rectus sheath and the linea alba is clearly visualized, an incision is made on the medial aspect of the posterior rectus sheath approximately 0.5 cm away from the linea alba to prevent iatrogenic injury to this critical structure.

Depending on location above or below the umbilicus, the adiposity from either the falciform or umbilical ligaments will be encountered. The linea alba is then cleared of this adipose tissue until the contralateral posterior rectus sheath is visualized. This is then incised, exposing the contralateral rectus abdominis muscle. At this point, the "crossover" has been completed (Fig. 80.9).

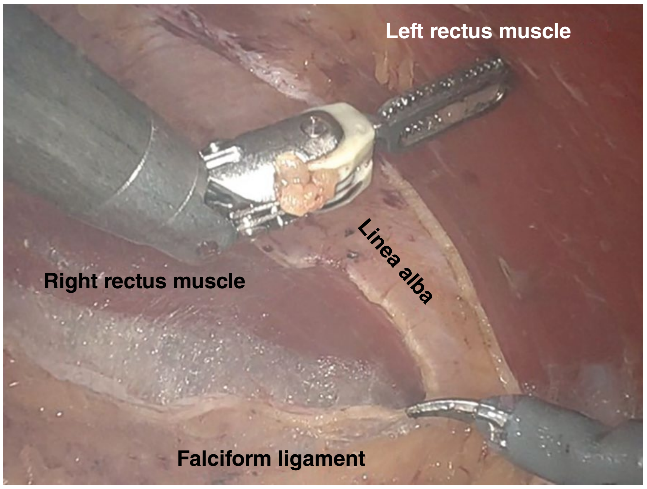

FIGURE 80.9 Completion of extended totally extraperitoneal crossover. Both rectus abdominis muscles and linea alba are clearly visualized. The posterior rectus sheaths and falciform ligament remain as the posterior layer.

As the dissection is continued, the hernia defect(s) are encountered and should be reduced. The retrorectus space is developed until adequate space for mesh overlap is achieved. The hernia defects are closed with absorbable barbed suture, and the linea alba is typically plicated to address any diastasis that is encountered. As mentioned, we routinely attempt to approximate the posterior rectus sheaths. If excessive tension is encountered, bridging peritoneum is sufficient. A medium-weight macroporous polypropylene mesh is placed, and the space is deflated under visualization. Refer to Video 80.4 for further details.

Transversus Abdominis Release

Patients who are candidates for MIS TAR are those patients with hernia defects 6 to 14 cm wide who have no more than 20% intraabdominal domain loss.[43] A TAR is useful for hernias that

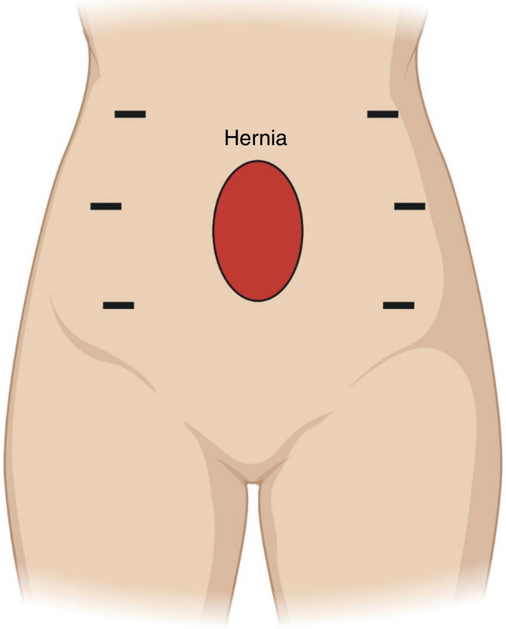

FIGURE 80.10 Port placement for minimally invasive surgery transversus abdominis release.

either would not have adequate mesh overlap from a retrorectus repair or hernias that are lateral to linea semilunaris. Any atrophic skin may be removed at the end of the case once the MIS portion is completed. Port placement is as illustrated in Fig. 80.10.

Initial access and the establishment of pneumoperitoneum can be performed with Veress needle, optical entry, or an open cutdown technique. After placing additional working ports, the first step often involves careful lysis of adhesions because these patients often have had multiple surgeries. The TAR dissection begins with a posterior rectus sheath release, stepping away laterally approximately 2 to 3 mm from the medial contributions of posterior rectus sheath to the linea alba and releasing this fascial structure from subxiphoid space to the arcuate line. Once in the retrorectus space, blunt dissection superficial to the posterior rectus sheath, in combination with judicious use of electrocautery, is used to dissect the retrorectus space. This dissection is limited laterally by the linea semilunaris. Neurovascular bundles that penetrate the posterior lamella of internal oblique are kept up with the underside of the rectus abdominis muscle, and care is used to identify and not injure these critical structures. Additional care is given to identify the deep inferior epigastric vessels on the dorsal portion of the rectus abdominis muscle. Some of the medial branches of this vessel may need to be ligated during the release of posterior rectus sheath. A TAR is then initiated by dividing two structures: first, the posterior lamella of internal oblique, followed by division of transversus abdominis muscle and/or aponeurosis and entering the space superficial to transversalis fascia and peritoneum.

This release is performed from the subxiphoid space, curving the release from subxiphoid fat pad, staying inferior to the insertion of the medial diaphragm fibers into the posterior rectus sheath, and staying medial and parallel to subcostal margin and, once below the level of costal margin, staying medial to neurovascular fibers and linea semilunaris. The release is extended past the arcuate line, which completely detaches the posterior rectus sheath from its lateral attachments to the linea semilunaris. The actual transversus abdominis muscle is only divided at the upper aspect of the abdominal wall because the muscle fiber contributions of the transversus abdominis muscle in that region are quite prominent. The transversalis fascia and peritoneal layer are then dissected from the underside of transversus abdominis muscle. This dissection can be taken past the midaxillary line and above the costal margin, exposing the fibers of the diaphragm cranially and the myopectineal orifices caudally, offering the ability to address any additional subcostal, subxiphoid, and groin hernias that may be present.

Consequently, the posterior flap can be advanced up to 10 cm medially or more. The anterior myofascial flap also receives aggressive advancement due to two fascial releases of posterior components of abdominal wall—the posterior rectus sheath release followed by the release of the posterior lamella of internal oblique and transversus abdominis muscle complex.

The posterior flaps are reapproximated in the midline with a running suture, and the mesh is placed in the developed retromuscular space. The defect in the anterior layer is closed, which is facilitated by decreasing pneumoperitoneum to 5 to 7 mm Hg. An uncoated mesh is trimmed to size and placed in the retromuscular space. A retromuscular drain may be placed, and the abdomen is desufflated. Refer to Video 80.5 for further details. ▶

Anterior Component Separation

Anterior component separation can also be performed with an MIS approach.[45] The surgeon typically begins by inserting ports on one side along the linea semilunaris and performing the dissection on the same (ipsilateral) side. Once the ipsilateral release is completed, the surgeon can place additional ports on the contralateral side. As with open technique, the MIS technique involves visualization of the entire anterior rectus sheath and identification of the linea semilunaris.

A fascial incision on the external oblique fascia, 1 to 2 cm lateral to the semilunar line, is then made in a cranial-to-caudal direction. The external oblique muscle itself can then be bluntly dissected off the underlying internal oblique muscle laterally to allow for medialization of the midline myofasciocutaneous flap. The superficial fascia and the linea alba are closed with a running suture technique. The mesh is inserted and deployed such that it lies flush on the anterior fascia. Onlay repairs mandate mesh fixation with suture, given its propensity to migrate in that position. A subcutaneous drainage is typically warranted. This relatively simple technique permits midline reapproximation and mesh placement outside the abdominal cavity. Complications such as flap ischemia and wound infections, although reduced with MIS approaches, are still seen.

Selection of Operative Technique

Hernia disease is a prevalent problem yet incredibly diverse. It is difficult to convey the complexity of hernia disease, which is determined by many factors, such as location, size, patient comorbidities, clinical acuity, and history of prior repairs. No VH classification system has been universally adopted, thus adding to the complexity of selecting management strategies. It is critical to approach each hernia patient with a tailored approach incorporating strong consideration for preoperative optimization, careful and individualized procedural selection, and comprehensive postoperative management. A surgeon requires a comprehensive understanding of abdominal wall anatomy and function as well as the various operative techniques and their potential pitfalls, as described earlier in this chapter, because complications can be devastating.

Patient selection is critical, and individual characteristics must be considered for a tailored approach. Factors including sex, BMI, social history, smoking status, functional status, and medical comorbidities (e.g., diabetes) can affect clinical outcomes. Refer to Chapter 79 for more details on preoperative management of the hernia patient. In terms of sex, studies have demonstrated female sex as independent risk factor for worse outcomes after hernia repairs, ventral or incisional, with increased adverse outcomes and chronic pain.[46] It is uncertain why such a disparity exists. Nevertheless, this is important to keep in mind because there may be less room for error in this patient population. It may also highlight the importance of a thorough preoperative conversation to set realistic goals and expectations. For female patients of childbearing age, it is important to consider their pregnancy and family plans. For those with asymptomatic or mildly symptomatic hernias, it is best to reserve definitive treatment until they have no plans for additional pregnancies because pregnancy may pose an increased risk for hernia recurrence. For patients with symptomatic hernias who are planning for future pregnancies, primary closure should be offered if possible. Although there certainly is a higher chance of recurrence, this approach does not disrupt any planes within the abdominal wall and preserves the more definitive tissue reinforcement-based repair options for the future if there is a recurrence. Complex abdominal wall reconstruction should be avoided in these patients, given the risk of postoperative abdominal wall compliance reduction.

Patient presentation and hernia symptomatology should be considered. Small asymptomatic hernias that contain preperitoneal fat or omentum can be monitored with a low risk of incarceration or bowel strangulation. Hernias that cause discomfort, pain, or intermittent obstructive symptoms should undergo repair. Hernias that present with acute incarceration should undergo urgent surgical intervention if reduction cannot be achieved promptly. Strangulated hernias certainly need surgical exploration. If there is bowel compromise that requires resection, primary repair is typically recommended because of the potential risk of mesh infection. If there is no bowel compromise, depending on the hernia characteristics and patient factors, definitive repair may be considered. However, it is typically not recommended to pursue complex repair with component separation in the acute setting. If it is a large or complex hernia that would require component separation, the primary or bridging repair and even skin closure alone may be considered, with plans for future abdominal wall reconstruction when the patient is better optimized.

Management of diastasis recti is a trending topic without consensus on its management. Diastasis can be a common incidental finding on examination or CT scan without evidence of abdominal wall dysfunction, and there is a lack of agreement on when diastasis is pathologic. Patients with diastasis recti may present with abdominal wall dysfunction with ongoing abdominal and back pain, in addition to having difficulty engaging their core. These patients typically benefit from physical therapy but can also benefit from surgical correction of their diastasis. Patients undergoing more extensive abdominal wall reconstruction for a complex hernia should have their diastasis addressed because it can serve as a weak point of the repair. For small VHs, diastasis should be considered a risk factor for recurrence after primary repair, and mesh placement should be considered.[47,48]

The development of a tailored operative plan begins with considering specific hernia characteristics, such as type and size. Types of VHs include primary, incisional, and recurrent. Primary hernias are typically smaller, with less adjacent tissue disruption compared with incisional hernias. Suture repair should only be considered in small primary hernias <2 cm. The choice of suture repair versus mesh-based repair for these small hernias is debated among surgeons, but, in general, both can be feasible options with good results. It is important to consider the presence of diastasis recti when considering suture repair of small primary hernia defects. Diastasis recti has been shown to be a risk factor for recurrence after suture repair of a primary VH.[48] Mesh-based repair is recommended for primary hernias >2 cm or incisional hernias.

The authors acknowledge the wide array of hernia repair techniques and differing practice patterns. However, the authors tend to follow the general algorithm shown in Fig. 80.11. We understand that this figure does not depict every permutation of VH management.

Selection of either an open or MIS approach is largely variable depending on surgeon experience and preference. Overall, MIS approaches are associated with lower wound complications and length of stay, particularly in more complex cases.[49] As such, our group generally prefers an MIS approach over an open approach for this reason if it is safe and feasible. An open approach is typically favored for small suture repairs or in cases where extensive tissue manipulation is necessary. These may include cases such as those with very large fascial defects (>15 cm), dense intraabdominal adhesions, necessity to excise large pieces of mesh or foreign bodies, bowel resection or fistula takedown, or need for extensive soft tissue rearrangement (e.g., panniculectomy). A hybrid approach in which a portion of the case is performed both MIS and open can also be considered and may reap the benefits of both approaches.[50] Long-term follow-up of outcomes, especially recurrence rates, will be important as the algorithmic approach to these complex hernia repairs continues to evolve.[51]

Regarding size, it is important to have a general concept of small, moderate, and large hernias; however, size is only one factor when deciding on the optimal operative approach. The hernia defect sizes discussed here are suggestions only and not concrete rules. Other considerations include anatomic details such as the width of the rectus abdominis muscles, hernia location, hernia-to-neck ratio, and abdominal wall compliance. For hernias 2 to 5 cm in size, preperitoneal, intraperitoneal, or retromuscular mesh repairs can be considered. For 6- to 8-cm defects, component separation will likely be needed with a Rives-Stoppa or retrorectus repair. Preperitoneal or intraperitoneal approaches can be considered for patients with good abdominal wall compliance, although it will be difficult to bring the fascial edges back together without too much tension. For 8- to 12-cm defects, Rives-Stoppa and potentially a TAR would likely be warranted, depending on the patient's abdominal wall compliance and rectus abdominis muscle width. Studies have shown that a ratio of the total rectus width to defect width greater than 2 can predict successful fascial closure with retrorectus dissection alone.[52] Anterior component separation can also be considered. For 12- to 15-cm hernias, it is likely that a component separation will be needed. For much larger, complex hernias, additional adjuncts such as Botox injections or progressive pneumoperitoneum may be necessary, but these are beyond the scope of this chapter.

Operative management of recurrent hernias is highly dependent on the patient's surgical history. It is critical to obtain all prior operative reports if possible. Imaging may add invaluable

RS
TAR
RS
TAR

Reversible patient risk factors should be optimized

Suture repair should be reserved for small primary ventral hernia defects

Offer MIS if safe and feasible. Tasks such as extensive lysis of adhesions, massive soft tissue rearrangement, or mesh excision favor open approach.

Plane of repair should be selected based on hernia characteristics, surgical history, and patient factors. Extraperitoneal mesh placement is favored in our practice.

Decision to perform RS or TAR is determined by hernia characteristics and ability to achieve appropriate mesh overlap. A ratio of hernia defect width to total rectus abdominis width of >0.5 favors TAR.

FIGURE 80.11 Management of ventral hernias. *ACS,* Anterior component separation; *IPUM,* intraperitoneal underlay mesh repair; *MIS,* minimally invasive surgery; *RS,* Rives-Stoppa; *TAPP,* transabdominal preperitoneal; *TAR,* transversus abdominis release.

information, including location of prior implants, fixation devices, and their relationship to the hernia defect. A recurrence after simple primary repair should be treated as an incisional hernia with an appropriate mesh-based repair for the hernia's characteristics. Recurrences after mesh-based repairs are tackled differently based on location of the prior mesh. The general concept is to perform a repair in a different plane compared with the last repair. For recurrences after an onlay repair, underlay or sublay repairs should be considered. Open or hybrid approaches may be needed if planning for mesh explantation or soft tissue resection. Recurrences after preperitoneal sublay or underlay repairs should be managed with either an onlay or retromuscular approach. Recurrences after retromuscular repairs can be challenging because most were likely performed for larger and more complicated hernias initially. If the recurrent hernia is small, an onlay or underlay repair may be considered. Large or more complex recurrence may necessitate a redo retromuscular repair, although it may be technically challenging.

Recurrent hernias can sometimes present with infectious complications, such as chronic abscesses or fistulas from mesh erosion. Staged approaches should be considered in the presence of active infection. The goal of the first stage is to achieve source control, which typically calls for the excision and removal of all foreign body material, including sutures and/or mesh. If a fistula has formed due to prior mesh placement, the mesh and involved viscera should be resected. Definitive hernia repair can be considered at least 6 months after clearance of active infection.

COMPLICATIONS

Complications are common after VHR. Complications can occur in the early postoperative period, similar to most wound complications, or in the long term, such as chronic pain or hernia recurrence. The clinical significance of each complication varies greatly. In this section, complications after VHR are discussed.

Infection

SSIs, as defined by the CDC, are complications caused by infection at the surgical incision site or from an intraabdominal process that leads to a collection of fluid, pus, or a culturable organism.[53] This includes abscess, necrotizing soft tissue infection, anastomotic failure, and mesh infection, among others. The infections are further classified by their location and what interventions are needed for resolution (Table 80.1).

The rate of SSI after VHR is highly variable in the literature, ranging from 4% to 21%.[54,55] Even a superficial SSI can be problematic. It is well established that patients who develop an infection are at higher risk of developing a hernia recurrence.[56] Furthermore, mesh infection can be a challenging problem, leading to chronic wounds and requiring reoperation.

An abscess is an infection involving a space-occupying collection of pus surrounded by inflammatory tissue. These collections can be in the superficial surgical site (skin and subcutaneous adipose), deep surgical site (fascial and muscle layers), and organ space (intraabdominal cavity). In hernia surgery, a mesh that is contained in the same space where an abscess has formed is

TABLE 80.1 **CDC SSI Classification**

TYPE OF SSI	TISSUE INVOLVED	FINDINGS
Superficial	Skin and subcutaneous tissue	Purulent drainage, positive wound cultures, or incision opened by physician with clinical signs of infection (does not include cellulitis)
Deep	Fascia and muscle	Purulent drainage, opened/aspirated by physician with positive culture or clinical signs of infection, abscess present on imaging
Organ/space	Deep to fascia/muscle in area that was manipulated during surgery	Purulent drainage, positive cultures, abscess present on imaging or examination

SSI, Surgical site infection.

considered infected and colonized. Mesh infections are discussed in the next section. Abscesses can present differently depending on their location. Swelling of the surgical incision, fever, purulent drainage from the surgical site, induration of skin, erythema, and pain care are all signs of a superficial abscess or SSI. Abscess formation in the deep or organ/space positions may present more insidiously. Pain, fever, prolonged ileus, increasing leukocytosis with left shift, and thrombocytosis can often indicate a deep or organ/space infection. Abscesses must be dealt with promptly. Systemic infection, necrotizing soft tissue infection, wound dehiscence, and mesh colonization are all possible complications of untreated wound infection.

The most effective treatment for abscess is drainage (in the absence of a prosthetic, such as mesh). Small abscesses (<3 cm) that are not amenable to drainage can be treated with antibiotics. RCT evidence has shown that for intraabdominal infections, antibiotic therapy can be stopped 4 days after adequate source control has been achieved.[57] In superficial wound infections, drainage can be performed at the bedside through the wound or through percutaneous drainage. Subcutaneous collections that can be adequately drained and have no signs of spreading or systemic infection do not require antibiotic therapy. Resolution of symptoms, leukocytosis, fever, and restoration of normal gastrointestinal function are all signs of resolving abscess. In cases of small (<3-cm) or undrainable collections, the optimal duration for antibiotics in these cases is not clear, with some practitioners advocating that many of these collections do not need treatment at all. Equally unclear is the indication for repeated imaging examination. Deterioration in symptoms or biochemical metrics are indications for intervention or repeat investigation, usually with cross-sectional imaging. Routine follow-up imaging is used by some surgeons, but the optimal indication for this has yet to be elucidated.

The incidence of mesh infection ranges from 1% to 8% in the literature.[58] Unlike superficial or deep SSIs, which must be diagnosed within 90 days according to CDC definition, a mesh infection can be diagnosed for up to 1 year after surgery.[53] In some cases, it can take even longer for a mesh infection to be diagnosed. It has been reported that the mean time from hernia repair to presentation of mesh infection is 19.9 months.[59] This delay likely leads to an underreporting of the true incidence of mesh infection in the literature. Mesh infection can present in a variety of different ways. A common presentation is the development of a chronic draining sinus (68%).[60] These sinuses may have purulent drainage that improves temporarily with antibiotics. A seroma that recurs even after drainage can be another sign of mesh infection (4%). Furthermore, enterocutaneous fistula (15%), exposed mesh (13%), recurrent abscess, skin induration, and pain can all indicate underlying infection.

There are several factors associated with the development of a mesh infection. Any SSI can lead to a mesh infection.[61] Other factors that are associated with the development of a mesh infection include diabetes (odds ratio [OR] 1.40; 95% CI 1.14, 1.71), smoking (OR 1.65; 95% CI 1.08, 2.52), obesity (OR 2.75; 95% CI 1.04, 7.27), urgent surgery (OR 3.10; 95% CI 1.61, 5.98), and the use of immunosuppressives (OR 2.35; 95% CI 1.49, 3.73).[62] Open surgery has a higher rate of mesh infection compared with laparoscopic surgery (OR 3.47; 95% CI 2.13, 5.62). Mesh type and location may also play a role in rate of mesh infection. Onlay mesh may be associated with a higher rate of mesh infection compared with sublay or underlay mesh (OR 3.16; 95% CI 1.73, 5.79).

The most common microbe indicated in mesh infection is *Staphylococcus aureus*, which can be found in 64% of cultures, and 42% of those are methicillin-resistant *S. aureus.*[60] Gram-negative bacteria are found in 35% of cultures, and the most common culprit is *Escherichia coli* (13%). Anaerobic bacteria and fungi are seen less commonly. Microbiology is also an important factor in determining treatment for mesh infection. Biofilm-forming organisms, such as *Staphylococcus*, are much more difficult to clear from mesh surfaces.

The type of mesh is important in determining if a mesh can be salvaged. Macroporous polypropylene mesh in an extraperitoneal position has the highest rate of mesh salvage at 72.2% of cases. Microporous polypropylene and polyester mesh have not been shown to be as infection resistant, with salvage rates of 3.1% and 3.2%, respectively. PTFE and composite meshes are unlikely to be salvaged.[59] Biosynthetic and biologic meshes were developed with the intention of being resistant to bacterial infection and therefore avoiding permanent mesh colonization. However, RCTs have shown comparable rates of SSI and increased recurrence rates when using biologic mesh versus synthetic mesh.[63] However, mesh explantation may be less likely with biologic mesh.[64] As such, with microporous polypropylene, biologic, or biosynthetic mesh, it is reasonable to attempt antibiotic therapy and drainage of any fluid collections as a first-line treatment for mesh infection. In the case of microporous polypropylene, polyester, PTFE, or composite mesh, antibiotic therapy can be attempted, but mesh explantation is likely to be required to adequately treat the infection.

There are several strategies for the treatment of a mesh infection. Conservative management with antibiotics alone can be attempted, but mesh salvage rates are low (21%).[59] Drainage, local debridement, and negative-pressure wound therapy (NPWT) can be used, with mesh salvage rates of 18% to 35%. Mesh explantation is often required. Mesh can be either partially or completely explanted. Infection recurrence is more likely with partial mesh excision compared with complete excision (58% vs. 25%; OR 4.15; 95% CI 2.30, 7.47). However, the rate of hernia recurrence is likely lower with partial compared with complete excision (10% vs. 40%; OR 0.25; 95% CI 0.04, 1.62).[65]

Seroma

A seroma is a sterile collection of inflammatory fluid. Seromas are common after many different types of surgery. The extent of intraparietal and/or subcutaneous dissection and the presence of a prosthesis make hernia surgery especially susceptible to seroma formation. The rate of seromas after VHR ranges from 3% to 52.4%, depending on the technique used.[34,66,67] The risk of seromas increases in emergency surgeries, patients with high BMI, large skin flaps, component separation, onlay mesh placement, and biologic mesh usage.[66] Seromas are often harmless. However, they can lead to secondary infection or compromise mesh integration.

The treatment of seromas depends on their size, location, and chronicity. Many seromas will resolve spontaneously. For seromas that are minimally symptomatic with no signs of infection, observation is the most appropriate treatment. Prophylactic antibiotics are not indicated. If the seroma is large or prolonged or if there are significant symptoms (e.g., pain or drainage from wound), seromas can be aspirated in an outpatient setting. Multiple aspirations or even drain placement may be required for complete resolution. Seromas refractory to percutaneous intervention may require surgical excision.

Drains are sometimes left in the surgical field to prevent seromas, but this is controversial and surgeon dependent. There is concern that drains may leave a patient more susceptible to infection. However, a recent meta-analysis suggests that drains reduce seroma rate (OR 0.34; 95% CI 0.12–0.96) with no increase in infection.[68] Drains should be considered if large subcutaneous flaps are developed, with retrorectus repair, or when component separation is performed. Drains are removed when output is minimal (30 mL/day) over 2 to 3 consecutive days or when a certain time point is met.[66]

Hematoma

Hematomas are collections of blood in a surgical space. The rate of hematoma after VHR has been reported as high as 7%.[5] Hematomas can present with hemodynamic compromise, pain, swelling, or orthostatic symptoms or can be clinically silent. Although many hematomas are self-limited, some require repeat intervention. Risk factors for postoperative hematoma include subcutaneous or intraparietal dissection, perioperative therapeutic anticoagulation, and component separation.[66,69,70] Patients who undergo posterior component separation are more likely to develop a hematoma than those with anterior component separation (OR 1.81; 95% CI 1.26–2.61).[34]

Management of postoperative hematomas is dependent on clinical presentation. Patients presenting with hemodynamic compromise should be adequately resuscitated, and individuals nonresponsive to resuscitation should return to the operating room for hematoma evacuation and source control. Those who are stable but who have had a clinically detectable bleeding episode often undergo cross-sectional imaging to identify its location. Consideration can be given to returning to the operating room if there is concern that the hematoma will interfere with mesh incorporation or is at high risk of infection. Stable, minimally symptomatic hematomas may be observed.

Chronic Pain

The definition of chronic pain can vary among studies, but it is generally accepted that pain still present at 1 year postoperative is considered chronic pain.[71,72] Approximately one-quarter of patients undergoing VHR will report some form of chronic discomfort or pain. Risk factors for postoperative pain include younger age, female sex, preoperative narcotic use, Carolinas Comfort Scale (CCS) preoperative pain score ≥ 2, and early postoperative pain.[71,73] Different techniques for mesh fixation have been implicated in causing more acute and chronic postoperative pain, but the data do not support this.[74] It is thought that minimizing penetrating fixation may decrease chronic pain.

Chronic pain can be debilitating, and patients should be counseled about the risk of postoperative pain while discussing the risks and benefits of the procedure. Patients should be counseled that postoperative pain after VHR can last for several months, and it is generally unwise to return to the operating room before 6 to 8 months. Patients presenting with postoperative pain after hernia repair should be thoroughly interviewed and examined to determine the exact quality and location of the pain. Nonsteroidal antiinflammatory drugs (NSAIDs) are helpful during these initial few months. If neuropathic pain is suspected, the addition of gabapentin or pregabalin can be considered. For pain that persists for more than 1 year, physical examination findings should be correlated with the surgery performed and imaging findings to see if a surgical cause for the pain could exist. Transfascial sutures and tacks have been implicated in certain patients with chronic pain, and removal of these can be considered if the pain correlates to their location. Anterior cutaneous nerve entrapment syndrome (ACNES) generally presents as pain along the lateral edge of the rectus muscle and is frequently misdiagnosed.[75] Mesh can sometimes be the etiology of chronic pain. Although mesh explantation may be offered, it is difficult to know preoperatively if removing a mesh will improve pain. Patients who undergo mesh explantation are likely to develop a recurrent hernia. Mesh removal should be considered as a last resort if there is no obvious problem with the mesh. If no surgical cause for chronic pain can be identified, patients should be referred to a pain specialist. Other modalities, such as regional anesthetic techniques, cryoablation, physiotherapy, and cognitive therapy, may be employed to treat chronic pain.

Intraparietal Hernia

An *intraparietal hernia* refers to herniation within the layers of the abdominal wall, such as the peritoneum or posterior rectus sheath. The traditional example of a primary intraparietal hernia is a Spigelian hernia. With the advent of retrorectus and component separation procedures, iatrogenic intraparietal hernias are becoming increasingly common. With a sublay mesh placement, a preperitoneal or retromuscular plane is developed. If there is breakdown of the posterior layer, intraperitoneal viscera may herniate within the layers of the abdominal wall. Intraparietal hernias can occur with underlay mesh placement as well. Abdominal contents can herniate between the mesh and anterior abdominal wall. Intraparietal hernias often present insidiously, much like internal hernias. Patients may complain of vague or intermittent crampy abdominal pain and obstruction. Often, cross-sectional imaging will be reported as normal postoperative anatomy because there is no defect in the anterior abdominal wall where one traditionally looks for a hernia. Surgeons should review the images in an attempt to identify the location of the mesh in relation to the bowel. Although rare, early postoperative bowel obstructions may be caused by an intraparietal hernia secondary to posterior layer dehiscence in retromuscular hernia repair. Interparietal hernias require operative intervention. Depending on the nature of the original operation, minimally invasive techniques may be used to reduce the intraparietal hernia and address the defect primarily with underlay mesh reinforcement if necessary and feasible (Fig. 80.12).

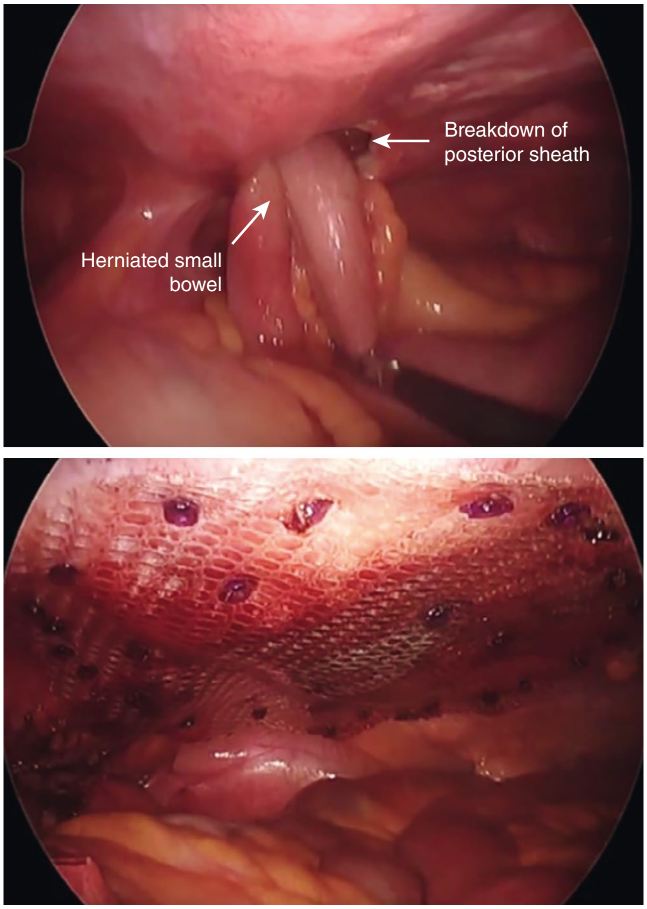

FIGURE 80.12 Before and after laparoscopic reduction of intraparietal hernia from posterior layer dehiscence with intraperitoneal underlay mesh repair.

Abdominal Compartment Syndrome

The repair of large and complex hernias can lead to intraabdominal hypertension. As a hernia gets larger, the amount of tension needed to close the abdominal cavity increases. Intraabdominal pressure increases proportionately. Intraoperatively, this can be noted by increases in airway pressure. Intraabdominal pressure can be estimated from bladder pressure, which is normally 5 to 7 mm Hg. It is considered intraabdominal hypertension when the pressure exceeds 12 mm Hg. In general, intraabdominal hypertension is not clinically impactful at lower pressures (12–20 mm Hg). However, at high pressure, intraabdominal hypertension can lead to ACS, which is characterized by respiratory, cardiac, renal, and gastrointestinal dysfunction. ACS is diagnosed by an intraabdominal pressure ≥20 mm Hg coinciding with acute-onset organ dysfunction. Prevention and early diagnosis of ACS are critical because the mortality rate of ACS is up to 60%.[76] The World Society of the Abdominal Compartment Syndrome (WSACS) recognizes ACS as a distinct class of compartment syndrome termed *quaternary compartment syndrome.* Risk factors for the development of ACS include positive fluid balance, hypoproteinemia, ratio of hernia sac to abdominal cavity volume (ACV) greater than 25%, and elevated BMI.[76,77]

The traditional treatment of ACS is decompressive laparotomy. However, the treatment of quaternary compartment syndrome can sometimes be nonoperative. Intraoperatively, mean airway pressures are monitored. Upon closure, if the mean airway pressure rises significantly (7–10 mm Hg), consideration should be given to keeping the patient intubated and paralyzed to allow for accommodation and muscle relaxation. In most cases, the intraabdominal pressure will decrease to appropriate levels in the next 24 to 48 hours, allowing for extubation. Patients who are extubated postoperatively who subsequently develop ACS should be intubated, sedated, and paralyzed, and abdominal pressure should be closely monitored. If unsuccessful, decompressive laparotomy may be needed. A high index of suspicion must be maintained to allow for the prompt diagnosis and treatment of ACS in the postoperative setting. Because of the risk of ACS, large, hernias involving domain loss should only be performed in an appropriate setting with access to intensive care unit (ICU) care.

Venous Thromboembolism

Patients undergoing VHR are at high risk of thromboembolic complications. Rates of venous thromboembolism in incisional hernia have been reported from anywhere between 0.2% and 7.9%.[78,79] Patients should begin postoperative chemical deep vein thrombosis (DVT) prophylaxis as soon as possible. Concerns of postoperative bleeding with early administration of DVT prophylaxis have not been demonstrated in the literature. Signs and symptoms of DVT or pulmonary embolism (PE), such as shortness of breath, calf swelling, unexplained tachycardia, and hypoxia, should be expeditiously investigated, and a high index of suspicion should be maintained in this patient population.

SPECIAL CONSIDERATIONS

Recurrence

The rate of hernia recurrence varies in the literature, ranging from 15% to 40%. It is therefore important for the surgeon to identify risk factors of recurrence to optimize the surgical outcomes.[80] Preoperative risk factors include smoking, diabetes, chronic obstructive pulmonary disease, American Society of Anesthesiologists (ASA) grade III to IV, and steroid use. Patients with higher BMIs also have higher odds of recurrence. In patients with VHs, 60% have BMIs greater than or equal to 30 kg/m^2.[81] Surgeons may encourage patients to lose weight before surgery. However, weight loss is challenging in these patients because the symptoms associated with the hernia can limit physical activities. Furthermore, delaying elective procedures increases the risk of hernia incarceration or strangulation.

Postoperative SSOs are associated with an increased risk of hernia recurrence. These include infections, seromas, hematomas, and wound dehiscence. The risk of SSI increases with higher BMIs, with the highest risk of SSI in patients with a BMI greater than 42 kg/m^2.[81] Minimally invasive approaches are thought to be protective against complications such as SSOs, given the decrease in wound and dead space area. A study demonstrated no significant differences in clinical outcomes with MIS retromuscular repairs in patients with a BMI either above or below 35 kg/m^2.[82] Smoking is associated with impaired wound healing because it affects oxygen delivery to the tissues. Smoking cessation for 4 weeks before elective surgery can decrease the risk of SSI in open cases.[83] Other systemic postoperative complications, such as pneumonia or urinary tract infection, increase the odds of recurrence. It is well known that hernia recurrence can lead to a vicious cycle of diminishing returns.[84] Increasingly, patients who develop hernia recurrences are being sent to multidisciplinary hernia centers to provide comprehensive care for these challenging cases.

Skin, Soft Tissue, and Dead Space Management in Abdominal Wall Reconstruction

Hernia repair should be done in a holistic fashion, with care to address the skin and subcutaneous tissue in conjunction with the underlying hernia defect. Over time, large hernias stretch the overlying skin. Leaving excess skin can increase the risk of SSOs and SSIs because of the large potential space for seroma formation that can lead to breakdown of skin closure. Thin skin may also necrose and ulcerate. To avoid wound breakdown and its associated complications, consideration should be given to excising the excess overlying skin.[85] Depending on the amount of redundant tissue, some patients may additionally benefit from a panniculectomy. During panniculectomy, excessive undermining of the remaining lipocutaneous flaps can disrupt blood flow from the perforators and compromise tissue vascularity. It is critical to consider other prior abdominal surgeries that may further compromise blood supply to the lipocutaneous flaps.

When dealing with SSO or SSI, healing by secondary intention with daily dressing changes is an option for small, superficial wounds. Large, clean, granulated wounds can benefit from skin grafts or flaps. Very rarely, regional muscular or fasciocutaneous flaps may be considered for larger wounds. Lastly, wounds may benefit from NPWT, which has been shown to improve blood flow and granulation tissue formation and decrease contamination.[86,87]

Physiologic fluid will accumulate in dead space. In the short term, this can cause issues with mesh incorporation and increase the risk of mesh infection and seroma formation. There are different ways to manage fluid buildup. When dealing with subcutaneous space, the surgeon can choose to place layered progressive sutures to approximate the defect. Closed suction drains can also direct fluid out of the surgical site. Surgeons may choose a combination of those techniques. More recently, NPWT over closed incisions, such as the PREVENA (3M, St. Paul, MN), have been used because it has been shown to reduce wound-healing complications, dehiscence, and seroma formation.

Acute Presentation

VHs that are reducible or chronically incarcerated with minimal symptoms can be repaired electively. Acutely incarcerated hernias or strangulated hernias require urgent surgical intervention. VH width-to-neck ratios greater than 2.5 are associated with an increased risk of emergency surgeries.[88] Emergent cases can present with acute pain, obstructive symptoms such as nausea or vomiting, overlying skin changes, and fever. Additional laboratory and radiologic studies, such as white blood cell count and lactate levels and CT imaging, can help with the diagnosis; however, strangulated hernias can be diagnosed on history and physical examination alone. Adequate volume resuscitation and broad-spectrum antibiotics should be initiated in the emergency department.

The goals of surgery are to relieve bowel obstruction and resect any necrotic bowel and/or tissue. Historically, VHs repaired in the emergent setting were closed primarily to avoid the risk of mesh infection. Recent evidence has shown more subtlety in decision-making.[89] Intraoperatively, the surgical field can be classified and help determine treatment options (Table 80.2).

For patients with intestinal obstruction but no signs of strangulation or need for bowel resection (class I wound), synthetic mesh is recommended. In cases with strangulated bowel needing resection without gross enteric contamination (class II wounds), using mesh does not increase the 30-day wound-related morbidity and decreases the risk of hernia recurrence. For patients with bowel necrosis and/or bowel perforation (class III–IV wounds), primary repair is indicated. In class III to IV wounds where the hernia is too large for primary repair, skin closure may be the only option. The surgeon should not attempt any component separation technique because these should be reserved for elective situations. The use of biologic mesh had been advocated in contaminated cases; however, this has fallen out of favor with time, given its high cost and unacceptable recurrence rates.[18]

TABLE 80.2 **Surgical Wound Classification**

Class I	Clean
Class II	Clean-contaminated
Class III	Contaminated
Class IV	Dirty-infected

TABLE 80.3 **Traumatic Abdominal Wall Hernia Grading Scale**

GRADE	REGION	DESCRIPTION
I	Abdominal wall	Contusion of subcutaneous tissue
II	Abdominal wall	Abdominal wall muscle hematoma
III	Abdominal wall	Disruption of a single abdominal wall muscle layer
IV	Rectus	Complete anterior abdominal wall muscle disruption
	Flank	Complete lateral abdominal wall muscle disruption
	Lumbar	Complete posterior abdominal wall muscle disruption
V	Rectus	Anterior disruption with herniation
	Flank	Flank lateral disruption with herniation
	Lumbar	Lumbar posterior disruption with herniation
VI	Rectus	Anterior herniation with evisceration
	Flank	Flank lateral herniation with evisceration
	Lumbar	Lumbar posterior herniation with evisceration

Traumatic Abdominal Wall Hernias and the Open Abdomen

In 2021, the Western Trauma Association (WTA) published its guidelines regarding the management of a rare traumatic entity: the blunt abdominal wall hernia.[90] The traumatic abdominal wall hernia (TAWH) occurs when blunt traumatic forces induce a disruption in the abdominal wall. These can occur in the lumbar, flank, and ventral locations. Annually, there are approximately 15,000 TAWHs, which represents an incidence of <1% in blunt trauma. As with other traumas, TAWH has a grading scale (Table 80.3).

The WTA retrospectively reviewed the registry in 20 trauma centers. In over a third of TAWH cases, there was concomitant bowel injury, indicating a significant need for immediate laparotomy. The decision on timing of TAWH repair is difficult because the patient may have concomitant injuries precluding surgery. Physiologic status and overall injury burden were both higher in the nonoperative group. Definitions of early versus late repair vary in the literature; however, this study defined early repair as during the index hospitalization, with late being sometime after discharge. Early repairs were typically performed within

48 hours. Less than a third of patients had mesh repairs, which may be a result of either small injury size or concerns over contamination. Also, 90% of the repairs were performed open. Late repairs are done after discharge, and the average timing was 1 year after injury. In this late-repair group, more than three-fourths of the patients required mesh placement. However, 68.4% of the late group was performed open, whereas the rest were performed with laparoscopy (15.8%) or robotics (15.8%). The rate of hernia recurrence was 11.5% in the early-repair group compared with 15.8% in the late-repair group, but this was not statistically significant.

The term *open abdomen* represents conditions when the fascia of the abdominal wall is not reapproximated after a laparotomy.[91] This can occur after a damage control laparotomy, in the treatment of ACS, or when a second-look intervention is planned as management for an intraabdominal disease (e.g., bowel ischemia). The open-abdomen patient is at risk for multiple complications, such as fluid and protein loss, fistulas, VHs, and challenging abdominal wall closure.

To prevent contamination and protect the viscera, various temporary closure methods can be used. Some surgeons opt for simple skin closure or the use of nonpermeable, inert membranes. Most surgeons will use negative-pressure dressings, which, in addition to intraabdominal fluid management, can prevent fascial edge retraction. Indeed, with negative-pressure dressings, fascial closure can be achieved 89% of the time, as compared with 59% with non–negative-pressure approaches. Patients are then often managed in the ICU setting with multidisciplinary teams involving critical care physicians, surgeons, and nutritionists.

Before closing an abdomen, the surgeon must be certain that intraabdominal infections are controlled and that the patient's physiology will be able to sustain the closure. Timing of closure is partly determined by the etiology of the open abdomen as well as the clinical state of the patient. In trauma, abdominal closure is preferred within 48 hours. In situations where primary closure is unfeasible, options include negative-pressure dressings, mesh bridging, and abdominal reapproximation anchors (ABRA system). Once the acute condition is resolved, many patients will develop incisional hernias.

Parastomal Hernias

With approximately 100,000 to 120,000 new ostomies being created in the United States annually and an incidence of parastomal hernia development in nearly half of these patients, parastomal hernias pose a significant clinical burden. Management of parastomal hernias is challenging, with high recurrence rates of nearly 70%, in addition to higher SSOs and morbidity of stomal-related complications. One of the key aspects of a sound hernia repair is to obliterate the hernia defect. However, this cannot be completely done in the setting of a parastomal hernia because a fascial aperture must exist for the conduit. Most parastomal hernias may be managed nonoperatively; however, a third of these patients will require operative intervention. Ascertaining whether the ostomy can be reversed is imperative because ostomy reversal is the best treatment for parastomal hernia repair. However, if the ostomy cannot be reversed, various surgical options exist. Re-siting of the ostomy has fallen out of favor recently because of the chance for a de novo incisional hernia at the prior ostomy site and a parastomal hernia at the new ostomy site. Given its unacceptably high rates of recurrence, primary repair of a parastomal hernia should only be performed in an acute setting where the main clinical goal is management of threatened bowel or other hernia complications. Regarding mesh repair, the two most common parastomal hernia repair techniques are the keyhole and Sugarbaker repairs.

The keyhole repair technique uses a mesh in which a slit and aperture are made so that the ostomy conduit can pass through (Fig. 80.13). A Sugarbaker technique is performed by lateralizing the ostomy conduit and then placing a mesh over the conduit and hernia (Fig. 80.14).[92]

The Sugarbaker repair has been found to have lower hernia recurrence rates compared with a keyhole repair; however, there were similar overall rates of complications, reoperations, stoma outlet obstruction, mesh infection, and postoperative bleeding.[93] Recently, a modified Sugarbaker technique has been described that uses a TAR and retromuscular mesh placement, but long-term data are still lacking regarding this technique.[94,95] It is important to consider that a synthetic mesh is in apposition to the bowel and may result in erosion, obstruction, or other severe complications.

Loss of Domain

The term *loss of domain* (LOD) is used to describe large VHs in which a significant amount of the abdominal contents are in the hernia sac outside of the confines of the abdomen walk. Quantitatively, the Sabbagh formula can be used to calculate the index of LOD. This volumetric method is the ratio of the incisional hernia volume (IHV) over the sum of the ACV and IHV. These volumes can be calculated from CT scans. A value of 20% or greater is generally considered a hernia with LOD.[96] In addition to affecting the patient's quality of life both aesthetically and functionally, hernias with LOD present a significant surgical challenge.[97] The etiology of these large hernias is usually secondary to midline laparotomies, although primary VHs with LOD can be seen. The incidence is on the rise as the population ages and with obesity becoming more prevalent. The giant hernias develop from a chronic process of linea alba disruption and lateral retraction of the abdominal muscles, followed by muscle atrophy and fibrosis. The abdominal viscera protrude into the hernia sac, the intraabdominal pressure will decrease, and there will ultimately be diaphragmatic muscle flattening. The dorsal muscle groups are no longer counterbalanced by the abdominal wall, and spine strain will ensue. In some cases, portal and mesenteric venous stasis may develop, resulting in bowel wall edema and digestive issues.

Most LOD hernias are not emergency cases; therefore, patients can be optimized for surgery.[96] Smoking cessation, nutritional optimization, blood glucose control, and improved cardiovascular function via prehabilitation are avenues to increase surgical success. Weight loss, although challenging, can decrease the volume of content that must be reduced in the abdominal cavity. Although there is a paucity of large studies to support this, omentectomy, right colectomy, and segmental small bowel resections can also reduce the visceral content that will be reduced in extreme cases. Adjuncts to complex VHR, such as progressive pneumoperitoneum, with or without botulinum toxin injection, can increase the ACV while allowing a functional abdominal wall reconstruction. The surgeon must be aware of possible negative sequelae caused by the reduction of hernia contents, such as respiratory compromise and intraabdominal hypertension, which may lead to ACS.

Cirrhosis

The incidence of abdominal wall hernias in patients with cirrhosis is 20% to 40%, and the increased morbidity and mortality in the setting of chronic liver disease pose challenges in management of these patients. A high-volume single-institution study found that

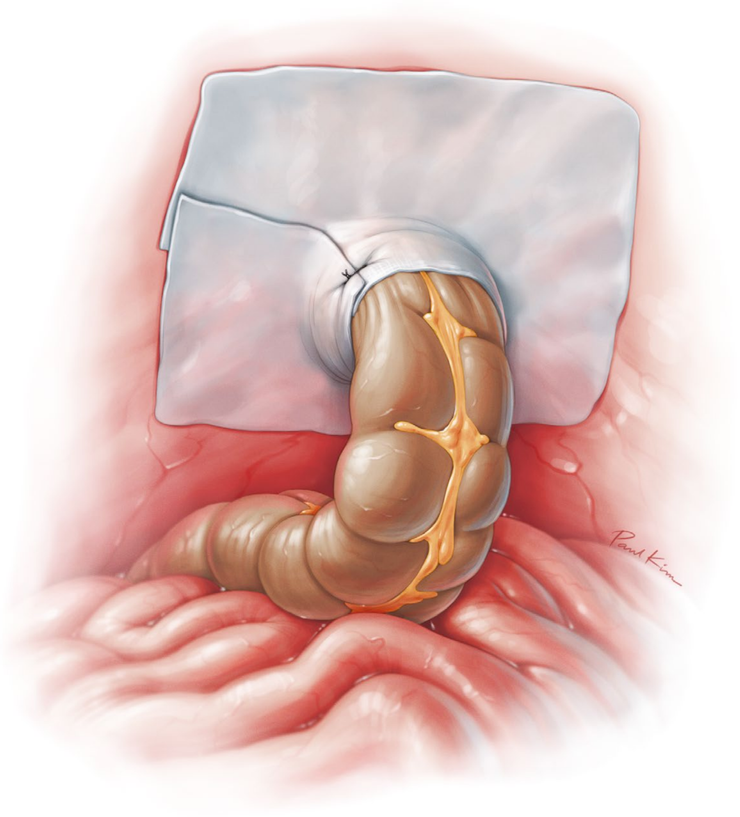

FIGURE 80.13 Keyhole repair of a parastomal hernia. (From Novitsky YW. Atlas of Robotic General Surgery. Elsevier; 2022, Figure 16.12.)

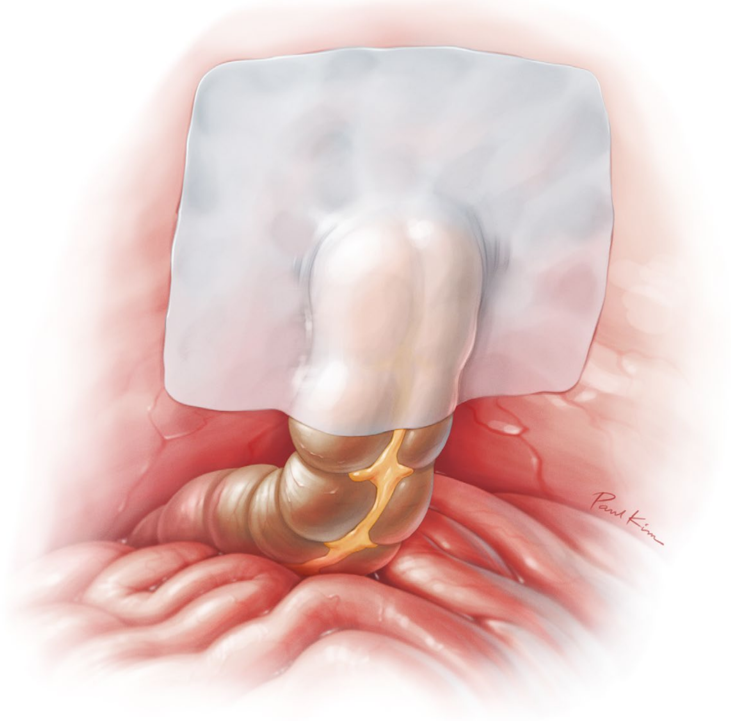

FIGURE 80.14 Sugarbaker repair of a parastomal hernia. (Atlas of Robotic General Surgery. 2022.)

emergent cases carried a 60% morbidity and mortality rate, with a 10% 90-day mortality rate. Nonemergent cases carried a 27% overall morbidity and mortality with a 3% 90-day mortality rate.[98] The high degree of postoperative morbidity and mortality in the emergent setting supports offering elective repair in patients with Model for End-Stage Liver Disease (MELD) scores of <20 if possible. These patients should be managed in high-volume hepatobiliary centers.

In elective situations, preoperative optimization is of utmost importance in cirrhotic patients. Hepatology should be consulted early, and the severity of the patient's liver disease should be ascertained. Ascites should be managed by diuretics and large-volume paracentesis with adequate volume replacement if necessary. The use of transjugular intrahepatic portosystemic shunt (TIPS) should be considered in refractory cases.

INTRODUCTION

Atypical hernias present a particular challenge to the surgeon. A robust knowledge of abdominal wall anatomy is required to diagnose and repair these defects. Although many types of atypical hernias are reported in the literature, this chapter will focus on flank, lumbar, spigelian, obturator, intraperitoneal, sciatic, paramedian, and perineal hernias. Atypical hernias exist in different areas of the abdomen and have different physiologic causes, but the principles of hernia repair remain consistent: reduce the hernia contents, reapproximate the fascial defect, and reinforce the repair using mesh with wide overlap while preserving adjacent anatomic structures. Coupled with these objectives in mind, the surgeon should factor in the patient's medical and surgical history, risk factors for wound healing, resources available to the surgeon, and the surgeon's skill set to select the optimal repair that can be offered. This chapter will review the atypical hernias, their location, diagnostic methods, and the approaches to repair in an open and minimally invasive fashion.

MODERN TECHNICAL ADVANCES

Over the past few years, with the increased use of robotic surgery, minimally invasive options for repair are becoming more prevalent. Similarly, there has been renewed interest in placing mesh in extraperitoneal spaces, such as the preperitoneal and retromuscular planes. This allows for better ingrowth to the abdominal wall and reduced interface with bowel compared with intraabdominal mesh placement. Extraperitoneal mesh can also be offered in an open fashion with similar results for recurrence; however, this approach is associated with greater wound morbidity and prolonged recovery. There may be more of a benefit with open approaches in those hernias with associated loss of domain, patients who cannot tolerate pneumoperitoneum, concurrent infection, severe intraabdominal adhesions, or previous mesh. A hybrid approach is also possible with a majority of the dissection and creation of the extraperitoneal space done minimally invasively with conversion to open to reapproximate the fascial defect and perform soft tissue reconstruction if needed.

SPIGELIAN HERNIAS

Relevant Anatomy

The Spigelian aponeurosis is formed from the membranous portions of the internal oblique and the transversus abdominis located laterally to the rectus and just medial to the semilunar line.[1] Defects in this Spigelian aponeurosis result in Spigelian hernias; however, because the external oblique does not contribute to the Spigelian aponeurosis, the hernia contents are typically covered by an intact external oblique (Fig. 81.1). Spigelian hernias almost always occur at or below the arcuate line, due to the absence of posterior rectus fascia in the area. The interparietal nature of these hernias can result in significant angulation of their contents; thus, they have a higher risk of strangulation and obstruction.[2] For that reason, it is recommended to repair these hernias even if they are asymptomatic.

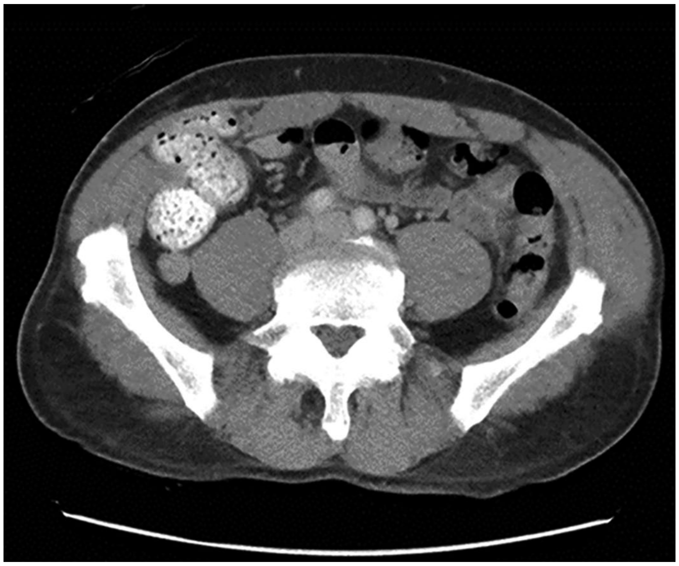

FIGURE 81.1 Right-sided spigelian hernia. Note the intact overlying external oblique muscle.

Etiology

Spigelian hernias are commonly small, present later in life, and can be difficult to detect on physical examination. These hernias can occur spontaneously or in the setting of previous surgical incisions because the naturally weak area is prone to forming hernias even from smaller incisions, including trocar sites.

Presentation

Due to the intact external oblique, a defect may not be appreciated on examination; however, a bulge or asymmetry may be present. Patients typically report pain or swelling on their lateral, lower abdominal wall. A dynamic ultrasound can be used for diagnosis; however, a noncontrast CT scan of the abdomen and pelvis is a more accurate test to allow for better delineation of the anatomy as well as assist in choosing the best operative approach.

In rare cases, a patient can present with diastasis of the semilunar line instead of a true hernia. Instead of an isolated bulge, it presents as an elongated ovoid ridge along the semilunar line (Fig. 81.2). Diastasis is more commonly seen in older and thin females. A CT scan is helpful to distinguish between a diastasis or a true defect as it is difficult to discern on physical examination (Fig. 81.3). Diastasis rarely causes symptoms and more often presents as a cosmetic complaint.

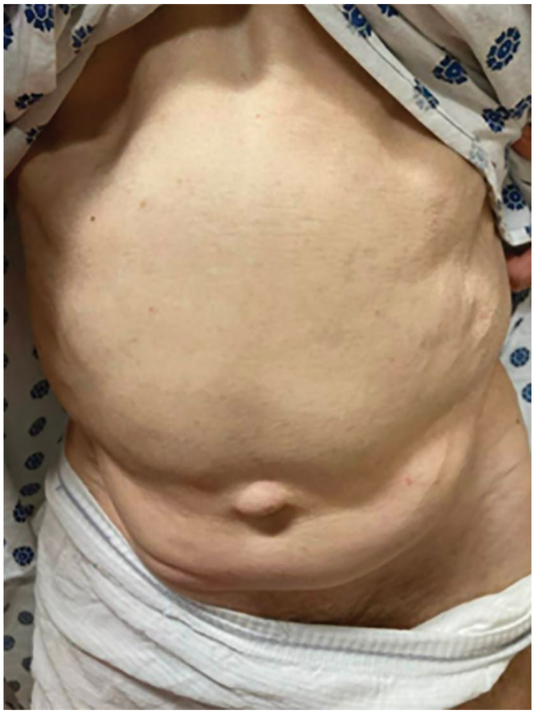

FIGURE 81.2 Patient with bilateral Spigelian aponeurosis diastasis.

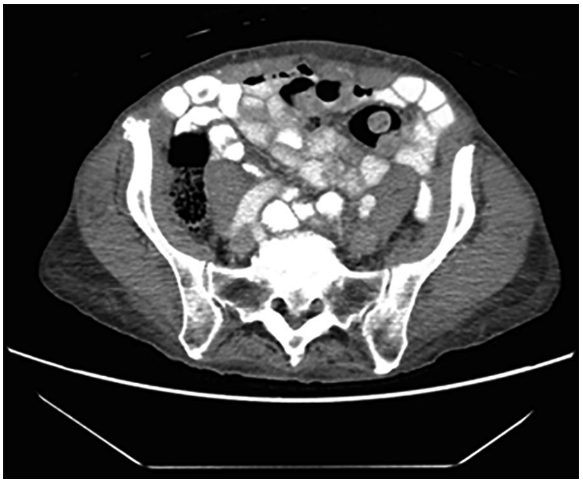

FIGURE 81.3 Axial CT scan of semilunar line diastasis showing no discernable defect in the transversus abdominis or internal oblique muscles.

Surgical Repair

Our preference for repair of Spigelian hernias is a robotic transabdominal preperitoneal approach (TAPP). A total of three ports are placed across the abdomen at or slightly above the level of the umbilicus and triangulated toward the defect. The contents of the hernia are reduced, and a peritoneal flap is then created to ensure at least a 5-cm overlap around the defect. It is easiest to start medially at the medial umbilical ligament and work toward the anterior superior iliac spine (ASIS). The medial dissection is completed first, bluntly dissecting toward the space of Retzius until the pubic symphysis and Cooper's ligaments are identified. Laterally, the preperitoneal dissection is taken to the psoas muscle, and transitioning into a pretransversalis plane is frequently necessary to ensure adequate mesh overlap (Fig. 81.4). Once the peritoneal flap has been created, the defect is closed and an appropriately sized mesh is placed in the preperitoneal pocket and is secured to the abdominal wall. The peritoneum is then closed over the mesh with a running suture. These are considered ambulatory procedures and patients routinely go home the same day in our practice.

For patients who might not be able to tolerate pneumoperitoneum, in recurrences after posterior repair or in larger defects, an open repair might be warranted. A transverse or oblique incision is made over the defect, which should be marked beforehand as the defect and associated contents may be difficult to palpate while the patient is supine. The external oblique is frequently intact over the hernia and will need to be incised in the direction of its fibers. Once the external oblique is opened, the hernia contents are identified and reduced into the abdomen. The fascial edges of the internal oblique and transversus abdominis anteriorly are

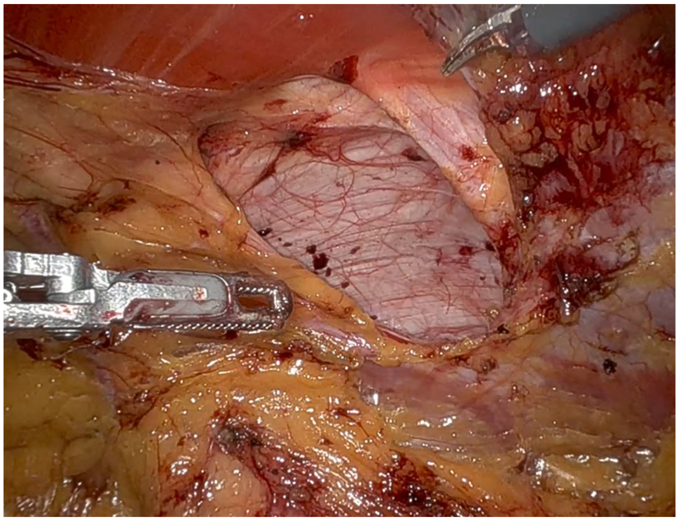

FIGURE 81.4 Intraoperative visualization of a right-sided Spigelian hernia occurring below the arcuate line.

cleared from the external oblique, and posteriorly any intraabdominal adhesions should be taken down. The defect is closed in layers, with the internal oblique and transversalis fascia reapproximated first, followed by the external oblique. Our preference is to use a slowly absorbable suture for fascial closure. For defects that are 2 cm or less, mesh augmentation may not confer a benefit; however, for larger defects, a mesh can be placed either preperitoneally or as an onlay. Our preference is to use an uncoated macroporous synthetic mesh in these situations. If mesh is placed in an onlay position, it must be well secured to prevent migration or bunching to maximize tissue ingrowth. Fibrin glue can also be used as an adjunct to suture fixation of the mesh; however, our practice is to use fixation with absorbable sutures. For onlay repairs we typically place a drain that is removed on follow-up visit around 2 weeks postoperatively. Spigelian hernia repairs are typically performed as outpatient surgeries.

Outcomes

The most common adverse outcomes after Spigelian hernia repair are hernia recurrence, seroma, hematoma, and infection; however, the risk profile is low. Minimally invasive repairs have a low rate of recurrence (0%–5%), a decreased length of stay, and earlier return of physical activity.[3–5]

Lateral Hernias

The European hernia society classifies lateral hernias as any fascial defect lateral to the rectus muscle.[6] The area can be broken up into four compartments: lumbar, subcostal, flank, and iliac (Fig. 81.5). These compartments are bordered by the subcostal margin superiorly, the iliac crest inferiorly, the lateral border of the rectus sheath medially, and the lumbar region laterally. Lateral hernias can be a challenge to repair due to their distortion of the abdominal wall and proximity to retroperitoneal nerves (Fig. 81.6). There can also exist a great challenge for closure of mesh overlap if the defect extends to costal margin or pelvic brim.

Relevant Anatomy

For the purposes of this section, we will group lumbar and flank hernias together because they are frequently diagnosed and treated the same. Although referred to interchangeably with flank hernias, lumbar hernias are located laterodorsal to the anterior axillary line between the costal margin and the inguinal region (Fig. 81.7). Although flank hernias are almost always incisional in nature, lumbar hernias can sometimes be found as primary hernias. Primary lumbar hernias are further classified anatomically based on the superior (Grynfeltt-Lesshaft) and inferior (Petit) lumbar triangles (Fig. 81.8). The superior lumbar triangle is bounded superiorly by the 12th rib and the inferior border of the serratus posterior, medially by the quadratus lumborum and sacrospinalis muscles, and laterally by the posterior border of the internal oblique.[7] The floor is formed by the aponeurosis of the transversus abdominis muscle, and the roof consists of the external oblique and latissimus dorsi muscles. The inferior lumbar triangle boundaries are the iliac crest inferiorly, the posterior

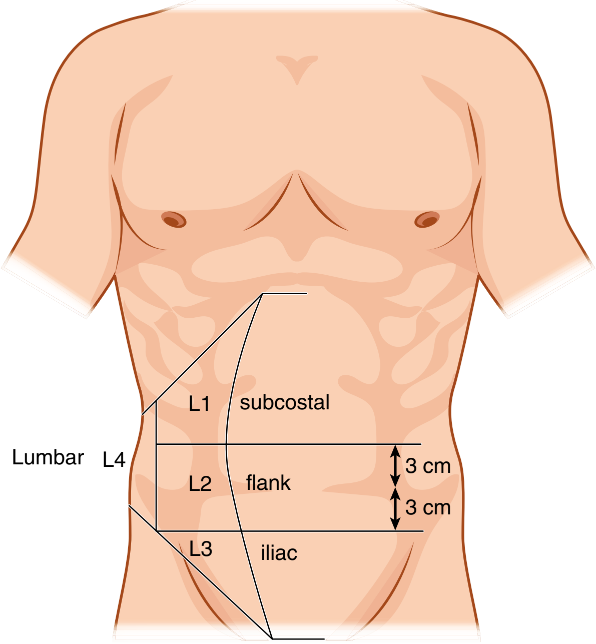

FIGURE 81.5 European Hernia Society classification of lateral hernias divided into four compartments: *L1*, the subcostal compartment; *L2*, the flank compartment; *L3*, the iliac compartment; and *L4*, the lumbar compartment.

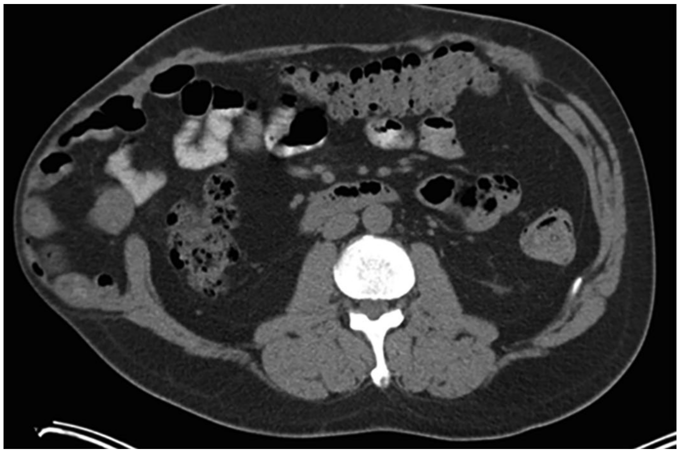

FIGURE 81.6 Iatrogenic flank hernia with incarcerated bowel contents.

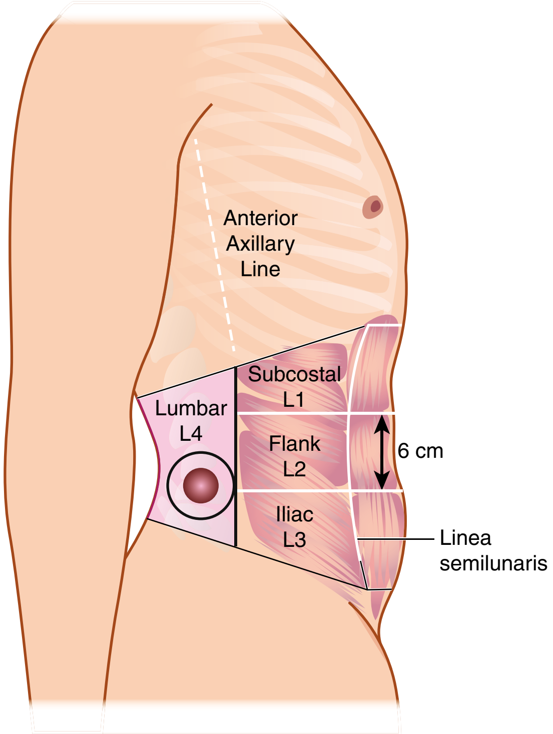

FIGURE 81.7 Boundaries of flank and lumbar hernias as defined by the European Hernia Society. Flank hernias are located lateral to the rectus sheath, whereas lumbar hernias are lateral to the anterior axillary line. (From Khetan M, Kalhan S, John S, Sethi D, Kannaujiya P, Ramana B. MIS retromuscular repair of lateral incisional hernia: technological deliberations and short-term outcome. *Hernia*. 2022;26[5]:1325-1336.)

border of the internal oblique laterally, and lateral border of the latissimus dorsi medially. The floor consists of the internal oblique muscle, transversus abdominis muscle, and posterior lamina of the thoracolumbar fascia.

Etiology

Primary hernias occur near areas that weaken the posterior abdominal wall such as perforating neurovascular pedicles through both the inferior and superior lumbar triangles. Acquired hernias result from traumatic injuries or from prior surgical incisions. Procedures that involve a lumbar incision (e.g., nephrectomy; Fig. 81.9) have a high incidence of lumbar incisional hernia with one series estimating the incidence of postoperative herniation to be as high as 30%.[8]

Presentation

These hernias require high clinical suspicion to accurately diagnose because they are uncommon and can be asymptomatic. Primary lumbar hernias are even more rarely encountered in routine general surgical practice, previously estimated to be encountered only once during a general surgeon's career.[9] CT is a critical component of diagnosis and subsequent operative planning. Given the anatomic location of these hernias, the herniated contents frequently consist of extraperitoneal fat and can result in asymptomatic presentations. Despite this, incarceration appears to occur frequently especially in primary lumbar hernias with one systematic review noting an incidence of 31%.[10] Another systematic review estimated that 9% of these patients will present acutely and require emergent surgical intervention.[11] Given the high rate of incarceration, repair of lateral hernias should be considered once diagnosed. Ultimately these hernias present rarely in surgical practice with incisional lumbar and flank hernias comprising less than 20% of all incisional hernia repairs and only 420 primary lumbar hernias reported in the literature.[12]

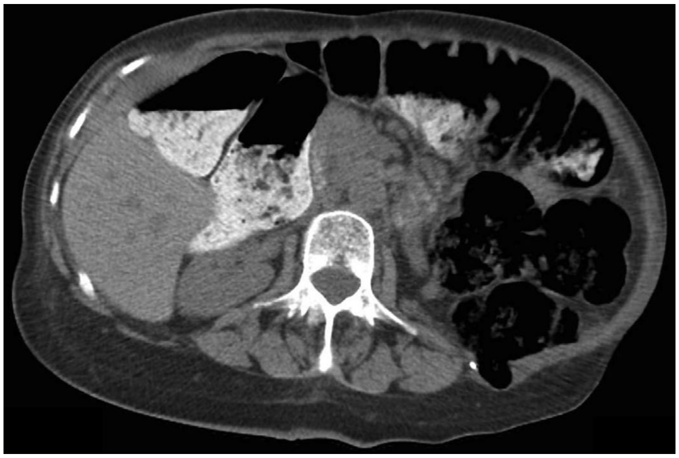

FIGURE 81.9 Patient with history of left nephrectomy with a resultant multiply recurrent left flank incisional hernia.

Surgical Repair

Current society guidelines recommend referral to specialized hernia centers for repair of the previously mentioned hernias.[13] Repair necessitates a solid understanding of the anatomy of the posterior abdominal wall with use of best hernia repair practices. In patients that are good candidates for a minimally invasive approach, we typically employ a robotic TAPP repair (Fig. 81.10). This repair takes advantage of the thicker layer of preperitoneal fat lateral to the semilunar line and has the benefit of excluding the mesh from the intraabdominal viscera. Depending on how lateral the hernia is, we either place the patients in a supine tilted fashion or place patients in a lateral decubitus position with the bed flexed to increase the space between the ASIS and the costal margin. The lateral extent of the preperitoneal dissection continues into the

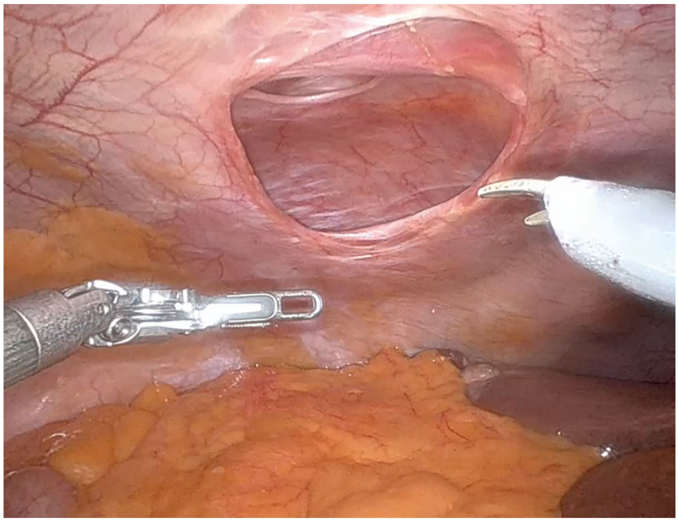

FIGURE 81.10 Visualization of right-sided incisional flank hernia.

pararenal space to the quadratus lumborum. The investing fascia of the quadratus lumborum and psoas muscles should be left intact to protect the ilioinguinal, iliohypogastric, genitofemoral, and lateral femoral cutaneous nerves. The ureter and gonadal vessels should be identified and preserved in this space as well. The dissection is sometimes carried below the costal margin or into the spaces of Retzius and Bogros if more overlap is needed. The goal of the repair is to reapproximate the obliques to the semilunar line (Fig. 81.11), and preperitoneal dissection is done to create a sufficient space for wide mesh overlap of the hernia.

In patients that are poor candidates for minimally invasive repair, an open approach can be done with the patient positioned similar to that for the preferred robotic approach. In patients with an incisional lateral hernia, the prior incision is used; otherwise, the incision is made directly over top of the hernia bulge or 2 to 3 cm superior to the ASIS. In the case of partial-thickness defects, frequently the external oblique muscle is intact and the dissection is carried down to the muscle, which is divided in the direction of the fibers to split the muscle and expose the hernia. After reducing the hernia contents, the preperitoneal plane is entered and a preperitoneal dissection similar to that described in our robotic approach is undertaken to perform a preperitoneal underlay mesh-based repair. We do not use transfascial suture fixation in these patients, opting instead for fibrin sealant fixation to avoid possible entrapment of surrounding neurovascular structures.

OBTURATOR HERNIAS

Relevant Anatomy

The obturator canal starts in the pelvis and exits in the medial portion of the upper thigh. This part of the thigh is referred to as the obturator or adductor region and is bound by the pubic arch, perineum, and gracilis muscle medially; the femur laterally; the pubic bone superiorly; and the insertion of the adductor inferiorly.[14] The obturator canal contains the obturator nerve, artery, and vein. The function of the nerve is to adduct the leg, and injury to this nerve may cause a noticeable decrease in function. Large, intact vascular connections between the obturator and the external iliac systems are called the corona mortis and can be visualized during minimally invasive repair. Not all patients have robust communications present. Most obturator hernias are located medially to the vessels and most commonly the sac can be found in front of the external obturator muscle. Typically, there is a small “fat plug” associated with the canal, which in a routine inguinal hernia surgery should be left in situ (Fig. 81.12).

Etiology

Obturator hernias are protrusions through the obturator canal and are remarkably rare, making up less than 1% of all hernias, with a majority of the literature published in the form of case reports.[15] Typically, obturator hernias affect elderly, thin females due to their triangular pelvis coupled with the atrophy of preperitoneal fat surrounding the obturator vessels. Other risk factors include chronic obstructive pulmonary disease (COPD), chronic constipation, or ascites, all of which cause increased intraabdominal pressure. Due to their location, they can be confused with either a femoral or inguinal hernia; however, when incarcerated they carry a high risk of strangulation with morbidity as high as 14%. This could be due to the difficulty in diagnosing this hernia

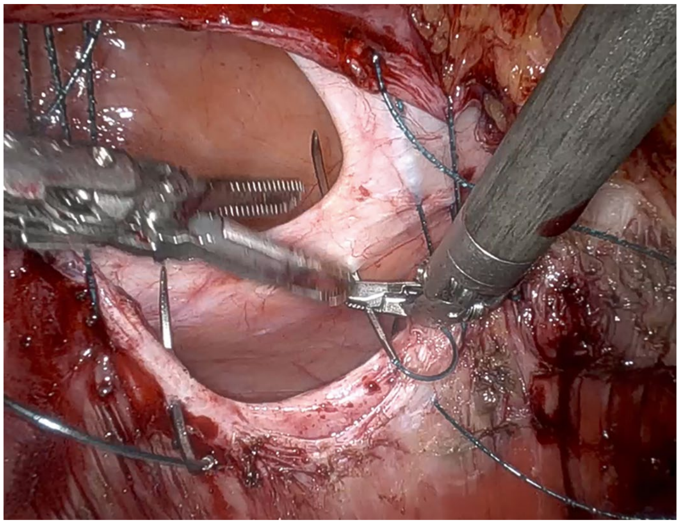

FIGURE 81.11 Reconstruction of components of the semilunar line during flank hernia repair.

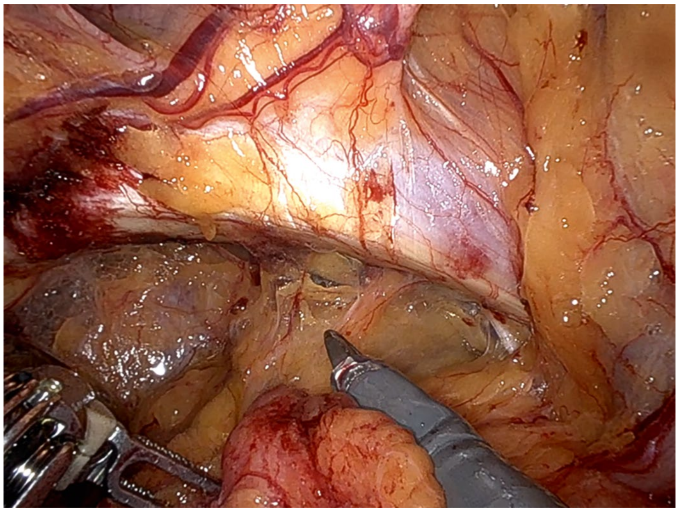

FIGURE 81.12 Visualization of obturator “fat plug” and associated nerve and vein underneath the pelvic brim.

leading to a delay in treatment, and a high clinical suspicion should be practiced in these scenarios.

Clinical Presentation and Evaluation

Because of the anatomic location of the obturator canal, diagnosing an obturator hernia on physical examination alone is incredibly challenging without adjunct imaging. One unique physical examination finding is pain in the anteromedial aspect of the thigh (Howship-Romberg sign), which is relieved with thigh flexion. This is caused by direct compression of the obturator nerve by the hernia contents. Unlike other hernias, one more common presenting symptom is bowel obstruction (up to 50%). Due to the bony pelvis and its associated interference, an ultrasound also may not be as useful as a CT scan in identifying an obturator hernia. Laparoscopy should be considered a diagnostic option as well.

Surgical Repair

A minimally invasive approach is preferred for obturator hernias because the visualization is much better compared with open repair. The setup for an obturator hernia repair is similar to the approach taken to repair an inguinal or femoral hernia. Three trocars are placed in a line at the umbilicus and triangulated toward the hernia. The patient is placed in steep Trendelenburg position, and the pelvis is inspected to identify the obturator hernia and a possible concurrent femoral or inguinal hernia. A peritoneal flap is started in a similar place to an inguinal hernia repair, near arcuate line, and is extending laterally to the abdominal side wall. Preperitoneal dissection is then performed down toward the pubic bone. Medially the space of Retzius is entered with identification of Cooper's ligament and pubic symphysis. Laterally the parietal plane is entered to protect the genital branch of the genitofemoral nerve and the lateral femoral cutaneous nerve. These nerves and the associated retroperitoneal fat should remain on the abdominal wall laterally and not taken down with the peritoneal flap. The dissection is then continued medially, parietalizing the spermatic vessels and vas deferens in males, whereas the round ligament is commonly ligated in females to assist with mesh overlap and exposure. Dissection proceeds until the obturator space is seen. At this point, inguinal and femoral hernias should be reduced. The obturator hernia contents should be reduced, and great care must be taken to avoid injuring the obturator vessels or nerve including with cautery. If there is no contamination or need for bowel resection, we recommend mesh reinforcement. The mesh should be placed medially in the space of Retzius covering the defect roughly 4 cm medially to the defect and 4 cm inferior to the defect. We typically fixate the mesh to Cooper's ligament. While closing the peritoneal flap, care should be taken so that the peritoneum does not slide anterior to the mesh because this may result in a recurrence. If done in an elective setting, patients are typically discharged on the day of surgery.

An open repair can also be undertaken in patients who do not qualify for minimally invasive surgery. A transabdominal approach with preperitoneal dissection through a lower midline incision is preferred. The patient should be positioned in Trendelenburg position to help facilitate exposure. If there is difficulty in reducing the contents, an inferomedial incision in the membrane can be made to enlarge the defect, taking care to avoid damage to the neurovascular bundle. The mesh should be placed in a preperitoneal pocket with generous overlap. In the scenario where a bowel resection is indicated, most of these defects are closed with permanent suture either in an interrupted or purse-string fashion. For larger defects in contaminated fields, a flap of peritoneum and retroperitoneal fat may be used to close the defect.

An alternative to the transabdominal approach is the obturator approach, which consists of making an incision just lateral to and along the border of the adductor longus muscle. The obturator bundle is identified at the interface of the adductor longus and the pectineus muscles, and followed proximally it reveals the obturator canal. A plug can be used to obliterate the obturator canal space. When fixating the plug, care must be taken to avoid the obturator neurovascular bundle.

PERINEAL HERNIAS

Perineal hernias are rare and repair is challenging. Most occur iatrogenically after abdominoperineal resection or perineal prostatectomy. This type of hernia results from a weakness in the pelvic musculature allowing pelvic viscera or other organs to protrude. Symptoms may include bowel obstruction or urinary dysfunction. Primary perineal hernias most commonly affect older, multiparous females and are frequently identified during a rectovaginal examination. MRI or CT scan imaging can confirm the diagnosis and help delineate anatomy to decide which approach for repair is possible.

Perineal hernias can be repaired either by perineal or abdominal approach or a hybrid of the two. The goal of repair is to reduce the pelvic contents and close the defect if possible. If primary closure is not possible because of the bony pelvic anatomy, a coated mesh with bony or ligamentous fixation can be used to prevent the protrusion of intraabdominal viscera. Augmented tissue or flap reconstruction may also be an option and varies regarding surgeon preference and available vascularized anatomy. Unfortunately, because of the rarity of these hernia defects, there are no randomized trials available that discuss which surgical approach is optimal. A meta-analysis of repairs shows no advantage of perineal over abdominal approach.[16] There was also no difference in recurrence between primary versus mesh versus flap repair with perineal repairs overall resulting in around a 22% recurrence rate.

INTERPARIETAL HERNIAS

Interparietal hernias result from herniation between the layers of the abdominal wall. Apart from the previously discussed Spigelian hernia, these hernias are almost always incisional. Given the partial-thickness herniation of these defects, they are frequently challenging to diagnose, and patients will frequently present with intestinal obstruction. CT is an important diagnostic tool in operative planning for these patients with hernias in atypical locations.

Given the increasing frequency of posterior component separation techniques being used in ventral hernia repair, two types of interparietal hernias bear mentioning: posterior rectus sheath herniation and semilunar line herniation. Both typically result from technical errors during the index hernia repair. As with other interparietal hernias, CT is a necessary step in the diagnosis and management of these patients and a high level of suspicion needs to be maintained.

Interparietal herniation can occur via a posterior rectus sheath defect after posterior component separation ventral hernia repair (Rives-Stoppa and transversus abdominis release techniques). During re-creation of the visceral sac via closure of the posterior rectus sheath, missed fenestrations or excessive tension on the closure can result in a herniation through the posterior rectus sheath (Fig. 81.13). Any patient presenting with signs and symptoms of bowel obstruction in the postoperative period after a retrorectus or retromuscular repair should be promptly evaluated for this complication.

Interparietal herniation can occur via semilunar line injury during transversus abdominis release procedures (Fig. 81.14). Herniation at this site results from improper intraoperative identification of the semilunar line with inadvertent division of the anterior lamella of the internal oblique during attempted division of the fibers of the transversus abdominis muscle. When this rare complication is identified, referral to a center specializing in complex abdominal wall surgery is recommended given the technical challenges associated with recurrent hernia repair after a transversus abdominis release procedure.

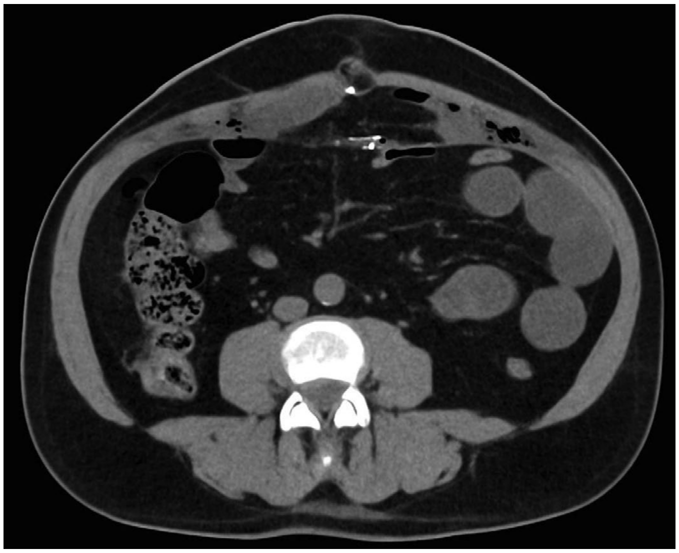

FIGURE 81.13 Interparietal hernia occurring after a retrorectus hernia repair because of posterior rectus sheath breakdown with small bowel herniating into the retrorectus space.

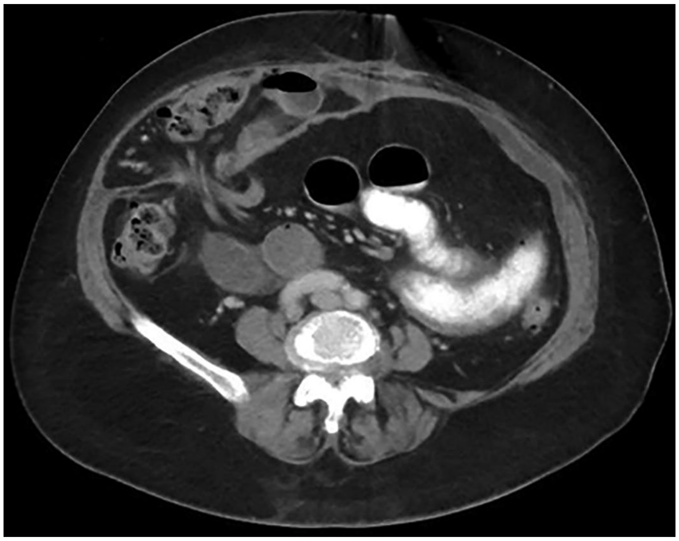

FIGURE 81.14 Interparietal hernia occurring in a patient presenting with small bowel obstruction from herniation at the right semilunar line secondary to a semilunar line injury from prior transversus abdominis release ventral hernia repair.

Discussion of operative approaches to manage these hernias is difficult given the variability in presentation as well as the anatomic structures involved. Furthermore, these are rare hernias with the literature describing repairs consisting of limited case reports.[17,17a] A straightforward repair of these hernias can involve laparoscopic-assisted intraperitoneal mesh placement, acting as a buttress to the posterior layer breakdown; however, larger defects need more extensive repair at a specialized center (Figs. 81.15 and 81.16). As with all hernias, management is based on the surgeon's clear understanding of abdominal wall anatomy coupled with wide mesh overlap of the hernia defect to limit recurrence.

SCIATIC HERNIAS

These hernias are extremely rare and occur at the site of the greater sciatic foramen (Fig. 81.17). Although there are no large series of cases, many case reports have been published.[18] A review of these

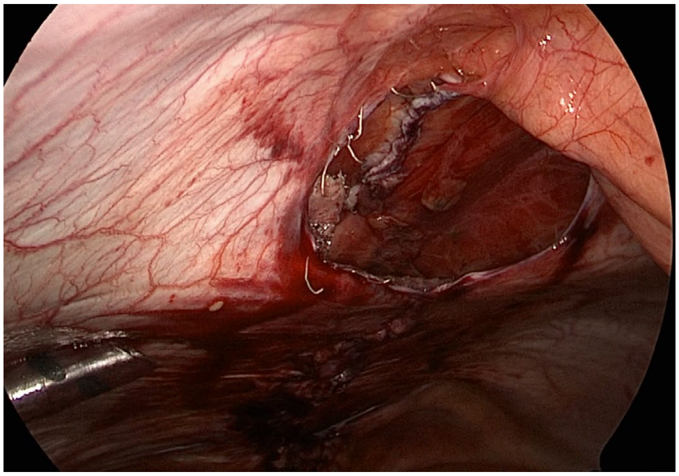

FIGURE 81.15 Posterior sheath breakdown after stapled Rives-Stoppa hernia repair.

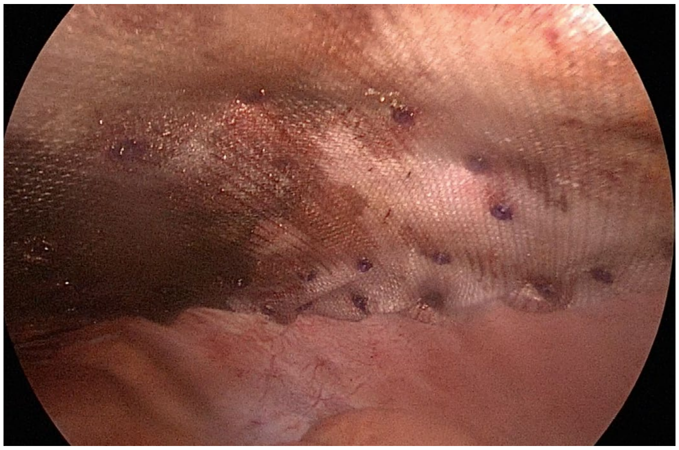

FIGURE 81.16 Intraperitoneal mesh repair of posterior sheath breakdown.

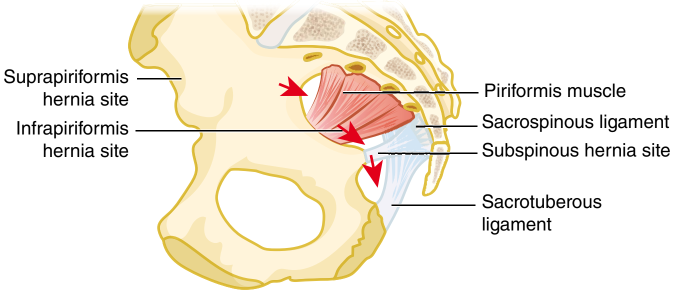

FIGURE 81.17 Anatomy and potential sites of hernia formation. (Adapted from Kavic, MS, et al. Hernias of the pelvic wall. In: LeBlanc, K, Kingsnorth, A, Snadersf, D, ed. *Management of Abdominal Wall Hernias*: Switzerland: Springer Cham; 2013:15-23.)

case reports from 1900–2008 yielded only 78 reports involving 99 patients.[19] Patients are typically asymptomatic until bowel obstruction occurs. Presentation of these hernias can manifest as a slowly enlarging mass or swelling near the gluteal area, or sciatic neuralgia. Repair of these hernias is recommended, and a minimally invasive approach should be undertaken when possible.[20]

A transabdominal approach is typically undergone for these hernias, and any incarcerated bowel is reduced with gentle traction. Steep Trendelenburg positioning can assist with visualization. Care is taken to not injure either the obturator nerve or vessels or the sciatic nerve or vessels, which are inferolateral to the obturator vessels. The ureter also courses inferior to this dissection plane and should be identified and protected. A flat synthetic mesh is used to cover the defect and is secured to Cooper's ligament. Plug mesh can be used; however, this may increase the risk of nerve damage. Alternatively, an open, transgluteal approach may be used with an incision over the hernia at the posterior edge of the greater trochanter. The hernia defect may be visualized after opening the gluteus maximus muscle, and the muscle and defect edges are closed in layers.

PARAMEDIAN HERNIAS

Off-midline incisions are encouraged by the European Hernia Society (EHS) to decrease risk of hernia formation.[21] Most paramedian incisions are made to perform operations in the retroperitoneal space, particularly anterior approaches to lumbar fusions, or repair of abdominal aortic aneurysm. A paramedian incision versus a midline incision has been shown to decrease incidence of hernia formation.[22] In the event a paramedian hernia occurs, principles of repair remain the same: reapproximating the mid rectus fascia with adequate mesh coverage. The particular challenge from a paramedian hernia repair is due to the close proximity to the midline and the semilunar line. If opting for a retromuscular repair and mesh placement, care must be taken to not disrupt these lines of anatomy. An open onlay approach or minimally invasive TAPP or intraperitoneal onlay mesh approach is reasonable and allows for wide mesh coverage, without the risk of injuring intact linea alba or semilunar line.

CONCLUSION

Atypical hernias are rare forms of hernias that may be encountered in a general surgery practice. Although their anatomy and presentation may be unique, their repair still follows traditional teaching of defect closure and mesh augmentation. A high level of clinical suspicion should be maintained for patients with symptoms and a history of off-midline or lateral incisions.

INTRODUCTION

Inguinal hernia repair (IHR) is one of the most common surgical procedures performed worldwide, with over 20 million performed annually. It is among the top-five most common major ambulatory operations performed in males over 18 years of age in the United States.[1] The landscape of hernia surgery has evolved significantly over the past decade, driven by the increasing adoption of minimally invasive (MI) techniques and the integration of advanced technologies such as robotic assistance. The vast array of repair techniques suggests that there is not a perfect solution.[2] Despite these advances, inguinal hernias continue to cause significant morbidity and healthcare costs. Although many patients are treated successfully, research suggests that recurrence rates range from 1.7% to 10%. Approximately 10% to 15% of groin hernia recurrences will need reoperative intervention. The negative consequences of groin hernia surgery can be devastating. About 10% to 12% of patients who have groin hernia surgery develop ongoing pain that can lead to long-term disability, and 1% to 3% of patients experience severe, lasting pain.

The lifetime occurrence of developing a groin hernia is 27% to 43% in males and 3% to 6% in females.[2] Inguinal hernias are classified as direct or indirect. A direct hernia defect is within Hesselbach's triangle, which is bordered by the inguinal ligament inferiorly, the inferior epigastric vessels laterally, and the lateral border of the rectus abdominis muscle medially. Indirect inguinal hernias pass through the deep inguinal ring, which is lateral to the inferior epigastric vessels. Two-thirds of inguinal hernias are indirect, and the remainder are direct. Femoral hernias comprise only 3% of groin hernias, but their true incidence may be higher given that they are often misdiagnosed. The female-to-male ratio for femoral hernias is about 10:1. Although femoral hernias occur more frequently in females than in males, inguinal hernias remain the most common hernia in females. Indirect inguinal hernias are the most common inguinal hernia type for both males and females. Femoral and indirect inguinal hernias occur more frequently on the right side as a result of a delay in atrophy of the processus vaginalis after the normal slower descent of the right testis to the scrotum during fetal development. The higher incidence of right femoral hernias is thought to be attributed to the sigmoid colon blocking the left femoral canal.

PERTINENT ANATOMY

Open techniques are typically associated with anterior approaches, whereas MI methods often involve posterior approaches to groin hernia repair. A thorough understanding of inguinal anatomy from both anterior and posterior perspectives is essential.

Anterior Anatomy

Internal Oblique Muscle and Aponeurosis

Deep to the skin and subcutaneous tissues are the superficial circumflex iliac, superficial epigastric, and external pudendal vessels, which arise from and drain to the proximal femoral vessels. These can be ligated for operative exposure if necessary. The external oblique (EO) is the most superficial of the lateral abdominal wall muscles, and its aponeurosis is the most superficial boundary of the inguinal canal. The muscle fibers of the EO run inferiorly and medially, and the aponeurosis is formed by a superficial and deep layer. The inferior edge of the EO aponeurosis forms the inguinal (Poupart) ligament and extends from the anterior superior iliac spine (ASIS) to the pubic tubercle. This structure turns posteriorly to form the shelving edge of the inguinal ligament. The inguinal ligament has a medial extension (the lacunar ligament) that inserts onto the pubis. The external or superficial inguinal ring is an ovoid aperture that is superolateral to the pubic tubercle and conveys the spermatic cord as it exits from the inguinal canal toward the scrotum.

Internal Oblique Muscle and Aponeurosis

The internal oblique (IO) muscle is the middle layer of the lateral abdominal musculoaponeurotic complex. In the upper abdomen, its fibers course superiorly and laterally and are directed more inferiorly in the inguinal region. In 5% of patients, the aponeuroses of the medial aspect of the IO and transversus abdominis join to form the conjoint tendon. The conjoint tendon is most evident at the pubic tubercle, where these muscles insert. The IO muscle fibers continue inferiorly to become the cremaster muscle fibers as they encircle the spermatic cord and attach to the tunica vaginalis of the testis. Preserving these fibers during open IHR is crucial to minimize the risk of chronic groin pain, which can result from injury to the genital branch of the genitofemoral (GF) nerve.

Transversus Abdominis Muscle and Aponeurosis and Transversalis Fascia

Much of the transversus abdominis muscle runs transversely throughout the abdomen; however, it courses in a slightly oblique and downward direction in the inguinal region. The aponeurosis of the transversus abdominis covers both anterior and posterior surfaces of the abdominal wall, with its lower margin arching with the IO muscle over the internal inguinal ring to form the transversus abdominis aponeurotic arch. Underlying the abdominal wall musculature is the transversalis fascia, which is also known as the *endoabdominal fascia.* The transversalis fascia tends to be more robust in the lower abdomen and is a component of the inguinal floor. The transversalis fascia and transversus abdominis aponeurosis and fascia condense to form the iliopubic tract (IPT). This aponeurotic band is posterior to the inguinal ligament, crossing over the femoral vessels and inserting on the ASIS and inner lip of the iliac wing.

Inguinal Canal

The inguinal canal extends between the internal and external inguinal rings and is located cephalad to the inguinal ligament. The inguinal canal is bound by the EO aponeurosis superficially, with its floor composed of the transversus abdominis muscle and transversalis fascia. The IO and transversus abdominis musculoaponeuroses form the cephalad wall, whereas the inguinal and lacunar ligaments form the inferior wall. *Hesselbach's triangle* refers to the margins of the floor of the inguinal canal. These are the inferior epigastric vessels as the superolateral border, the rectus sheath as the medial border, and the inguinal and pectineal ligaments as the inferior border. In males, the inguinal canal contains the spermatic cord, and in females, it contains the round ligament. The spermatic cord is composed of cremaster muscle fibers, the vas deferens, the testicular vessels, the genital branch of the GF nerve, lymphatics, and the processus vaginalis (Fig. 82.1).

The iliohypogastric nerve, ilioinguinal nerve, and genital branch of the GF nerve are commonly exposed in anterior operative approaches to inguinal hernias. The iliohypogastric and ilioinguinal nerves provide sensation to the skin of the groin, base of the penis, and ipsilateral upper medial thigh. Proximally, the iliohypogastric and ilioinguinal nerves travel beneath the IO muscle

to a point just superomedial to the ASIS. These two nerves then penetrate the IO muscle, traveling under the EO aponeurosis. The main trunk of the iliohypogastric nerve courses on the anterior surface of the IO muscle and aponeurosis medial and superior to the internal ring before piercing the EO aponeurosis to innervate the skin. Occasionally, the iliohypogastric nerve gives off an inguinal branch that joins the ilioinguinal nerve. The ilioinguinal nerve runs anterior to the spermatic cord and branches at the external ring. The genital branch of the GF nerve innervates the cremaster muscle and provides sensory innervation to the lateral scrotum and labia. This nerve accompanies the cremaster vessels as a neurovascular bundle in males but follows the round ligament in females.

Posterior Anatomy

The Myopectineal Orifice

The medial aspect of the superior gap between the pelvis and the thigh is the myopectineal orifice. In 1956, the French anatomist and surgeon Henri René Fruchaud first described the term and the concept of a weakened myopectineal orifice as the cause of hernias in the inguinal region.[3] Wide reinforcement of the myopectineal orifice has become the foundation for our modern hernia repair of the adult groin. A posterior view of the right hemipelvis and associated musculature is shown in Fig. 82.2.

Femoral and Iliopectineal Area

Starting with the isolated right bony hemipelvis, the inguinal ligament, or Poupart's ligament, can be seen in Fig. 82.3. The inguinal ligament is the inferior border of the EO muscle and extends from the medial bony projection of the pubic tubercle to the ASIS.

The gap below the inguinal ligament is divided into two spaces by another condensation of the iliopsoas fascia, known as the *iliopectineal arch*. The medial aspect is vascular, and the lateral is muscular (Fig. 82.4).

The lateral muscles include the iliacus and major psoas muscles (iliopsoas complex). They share a common tendon as they exit the pelvis inferiorly, which inserts on the medial aspect of the femur. The femoral nerve (FN) runs deep within the psoas muscle and emerges laterally as it passes beneath the inguinal ligament. The FN is rarely encountered during routine MI IHR. The tendinous structure anterior to the psoas major is not its tendon, which can only be seen from the anterior view of the pelvis, but rather the tendon of the psoas minor muscle. The lateral femoral cutaneous nerve exits from the lateral border of the psoas and travels over the iliacus muscle. The nerve can be singular, but many branches are often found. Injury to the lateral femoral cutaneous nerve can lead to pain, numbness, or tingling in the lateral thigh, a condition known as *meralgia paresthetica*.

The lateral muscular aspect of the iliopectineal arch is covered by the iliopsoas fascia, which protects the surrounding nerves and should be preserved during hernia repair to prevent nerve injury. The pectineus muscle covers the floor of the vascular gap and inserts into the pectineal line, a ridge of bone, via the pectineal or Cooper's ligament (Fig. 82.5).

Posterior to the pubic arch and between it and the ischium is an opening known as the *obturator foramen*. The obturator muscle narrows inferiorly to exit the pelvis via the obturator foramen and then inserts on the femur. Anteriorly, it leaves a small gap for the passage of the neurovascular structures. This

gap conveys the iliac artery and vein, which then continue as the femoral artery and vein once they pass the inguinal ligament. Medial to the vein is a recess of the transversalis fascia, the femoral canal, which is visible anteriorly. A portion of the most medial aspect of the inguinal ligament fans out and inserts into the pectineal rim to form the lacunar ligament. There are two major misconceptions commonly propagated. First is that the medial border of the femoral canal is the lacunar ligament (Fig. 82.6). This is typically not the case unless there is a sizeable femoral hernia significantly extending medially. Second is that the inguinal and lacunar ligaments are visible from the posterior wall. The correct anatomy becomes apparent when details of the IPT are considered. The IPT is formed as a condensation of the transversalis fascia, running parallel but posterior to the inguinal ligament (Fig. 82.7).

The IPT extends from the iliopectineal fascia (not the ASIS as commonly described) to the pubic tubercle, where it provides a triangular fascial extension that inserts into Cooper's ligament. The medial border of this extension is the medial limit of the femoral canal, which now appears smaller in Fig. 82.7. The medial border of the femoral canal is sometimes divided to reduce an incarcerated femoral hernia safely. The space between the inguinal ligament and the IPT medially serves as the floor of the inguinal canal and the ceiling of the femoral canal.

Medial Supporting Structures of the Posterior Wall

From medial to lateral, the linea alba ends at the pubic area with a triangular structure known as the *adminiculum.* The rectus abdominus (RA) muscle inserts a significant tendon inferiorly into the pubic rim. The IO muscle arises laterally from the iliopsoas fascia and fans out inferiorly, sometimes backing down into the inguinal ligament. However, it commonly travels medially to reinforce the anterior rectus sheath (Fig. 82.8).

The transversus abdominus (TA) muscle, which is posterior to the IO and mostly aponeurotic at this level, reflects into the inguinal ligament. The arch formed by the IO and TA is called the *falx inguinalis* or *TA arch.* The middle tendon of the TA joins the IO tendon in about 5% of patients to form the conjoint tendon. The conjoint tendon inserts into the pubis, which adds further reinforcement to the posterior wall (Fig. 82.9).

The EO muscle, which is aponeurotic in the medial inguinal area, covers the anterior inguinal canal and leaves an inferolateral

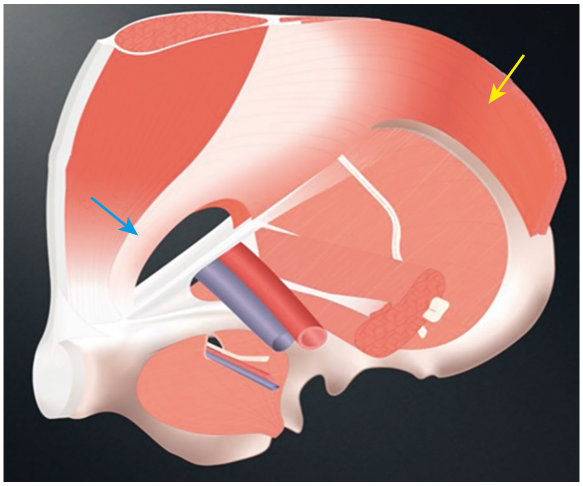

FIGURE 82.9 Relationship of the transversus abdominis muscle and the posterior wall *(yellow arrow)* and conjoint tendon *(blue arrow)*.

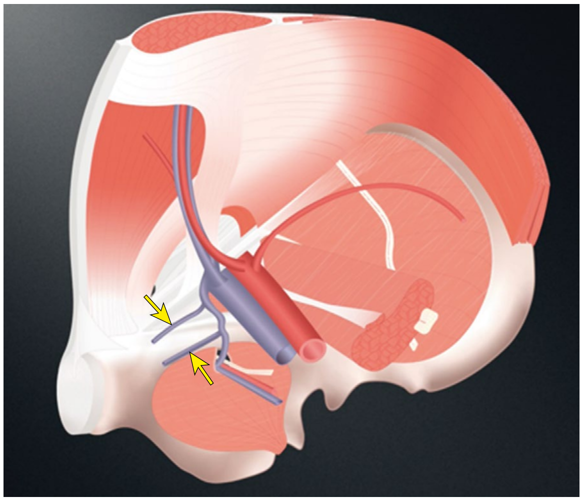

FIGURE 82.10 Origin of corona mortis vessels *(yellow arrows),* which connect the inferior epigastric and obturator vessels.

gap known as the *external* or *superficial inguinal ring.* The inferior border of the EO muscle is the inguinal ligament.

The posterior sheath of the RA muscle classically ends a third of a distance between the umbilicus and the pubis at the arcuate line, also known as the *semicircular line of Douglas.* However, it can extend lower, sometimes reaching the pubis. A fascial condensation of the transversalis fascia and the TA muscle extends medial to the arcuate line to reach the IPT. This is known as the *interfoveolar* or *Hesselbach's* ligament and is another reinforcement structure of the posterior wall. Hesselbach's ligament splits the inguinal canal into a medial and a lateral portion and usually supports the epigastric vessels. The accessory obturator vein (and sometimes also the artery) crosses the pubic rim to connect the obturator with the epigastric vessels and often gives off medial parallel branches called the *superior and inferior ramus branches.* This arrangement of vessels constitutes a circular connection known as the "crown of death" or *corona mortis.* Careful dissection in this area is of utmost importance to avoid inadvertent bleeding (Fig. 82.10).

Hesselbach's ligament, the conjoint tendon, and Henle's ligament buttress the transversalis fascia, which covers the entire area and prevents the development of hernias. Weakness of the transversalis fascia and absence or displacement of the supporting structures of the posterior wall cause direct hernias. Direct hernias typically occur medial to the epigastric vessels within Hesselbach's triangle. However, they can also appear lateral to the epigastric vessels if the supporting structures are absent or displaced.

The Internal Ring and the Cord Elements

The lateral border of Hesselbach's ligament forms the internal edge of the deep or internal ring. In the male embryo, the gubernaculum testis pulls the vas deferens and the internal spermatic vessels into the internal ring. In the female, the round ligament is the analog of the gubernaculum and enters the internal ring to insert into the labia majora. The first structure that the cord elements pass through on their way to the inguinal canal is not the opening of the transversus abdominis at the internal ring but a lesser-known microfascia called the *transversalis sling* (TS), which partially surrounds these elements. The TS is a condensation of the TA aponeurosis and the transversalis fascia and has horizontal and vertical limbs. As such, the TS serves as an important anatomic landmark during MI IHR. The GF nerve runs on the anterior surface of the psoas major, which has variable branches, although still predictable in location. Its fibers run below the TS to provide sensory innervation to the anteromedial thigh. Nerve distribution is variable, but the genital branch typically runs parallel to the iliac artery and passes under the horizontal limb of the TS, after which it angles anteriorly to enter the inguinal canal. The femoral branch of the GF nerve runs more laterally and courses under the horizontal limb of the TS (Fig. 82.11).

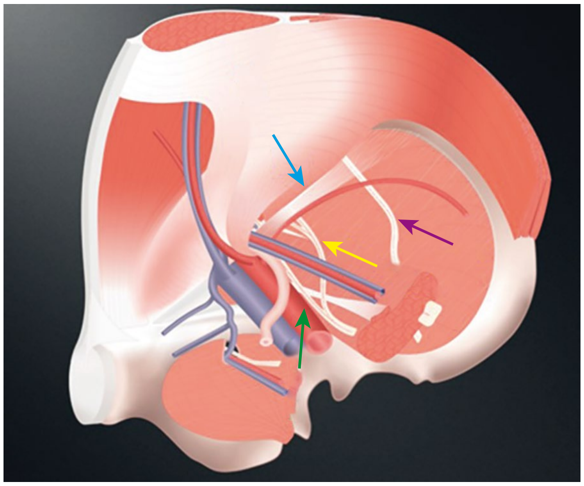

FIGURE 82.11 Transversalis sling *(blue arrow)* and its relationship to the genitofemoral nerve. Both the genital branch *(green arrow)* and femoral branch *(yellow arrow)* travel posterior to the horizontal limb of the transversalis sling, with the femoral branch coursing more lateral than the genital branch. The lateral femoral cutaneous *(purple arrow)* runs lateral to both branches of the genitofemoral nerve.

The cord elements are bound together by a fascial envelope derived from the urogenital fascia. Herniated preperitoneal fat, often referred to as *lipoma of the inguinal canal* because of its pseudocapsule, can be found anterolateral to the cord elements and above the horizontal limb of the TS. This arrangement helps differentiate canal lipomas from lymph nodes. Lipomas of the canal also tend to be lighter in color, whereas lymph

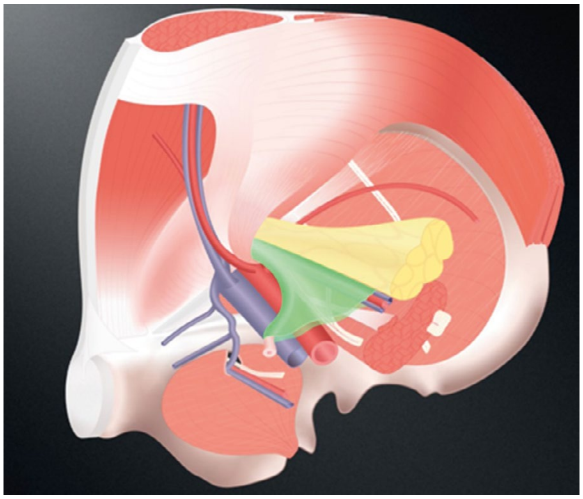

FIGURE 82.12 The urogenital fascia *(green)* envelops the cord elements. Canal or cord lipomas are located anterolateral to the cord elements *(yellow).*

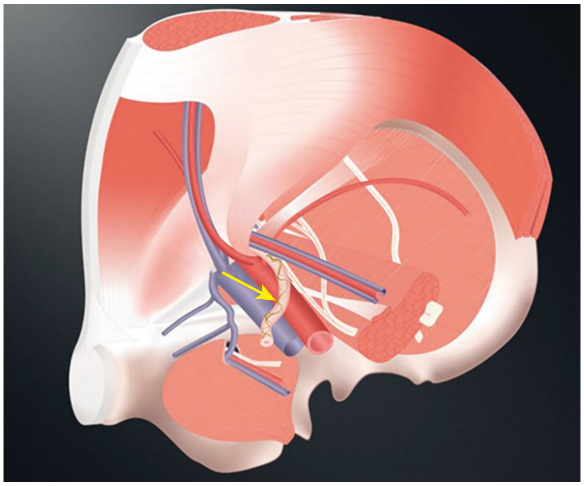

FIGURE 82.13 Autonomic innervation of the testicle is provided by the paravasal nerves *(yellow arrow),* which travel along the vas deferens. Preserving these nerves is important during dissection of the hernia sac.

nodes are darker yellow. Lymph nodes should be left undisturbed unless there is a compelling reason for biopsy because their dissection is associated with bleeding, lymphatic leakage, and potential nerve damage. Canal lipomas should also be distinguished from a fatty spermatic cord. Although the distinction is not always clear, retracting the suspected lipoma laterally and the cord elements medially can aid in differentiating the two (Fig. 82.12).

Nerve Distribution

Awareness and preservation of the somatic and autonomic neural structures and their fascial coverings are essential to prevent neuropathy, which is one of the most dreadful complications of IHR. Despite the wide variability of nerve distribution in the posterior wall, there are anatomic clues that can help prevent nerve injury.

Nerves in the posterior inguinal wall are in a trapezoidal or triangular region, medial and inferior to the IPT and lateral to the spermatic vessels. This area has been dubbed the "triangle of pain." No mechanical fixation or careless dissection should take place in this area. However, studies have shown in cadaver dissections that nerves can enter the thigh above the IPT, with a few entering 1 cm above the IPT.[4] Based on this, it has been recommended to expand the triangle of pain by shifting the superolateral border 2 cm above an imaginary line drawn between the ASIS and the internal inguinal ring. Injury to the genital branch of the GF nerve tends to occur with aggressive dissection within the triangle of pain, which should be avoided. This is also typically the cause of injury to lateral nerves, such as the iliohypogastric and ilioinguinal nerves that course between the TA and IO muscles, which are not routinely visible during MI IHR.

The paravasal nerves are responsible for the autonomic innervation of the testicle. These nerves travel from the pelvic and hypogastric plexi and run along the vas deferens to innervate the testicle. Injury to the paravasal nerves can result in deep testicular visceral pain, as opposed to the scrotal pain of somatic dermatomal distribution. Dissection of the hernia sac with minimal manipulation of the cord elements is a fundamental strategy to avoid this complication (Fig. 82.13).

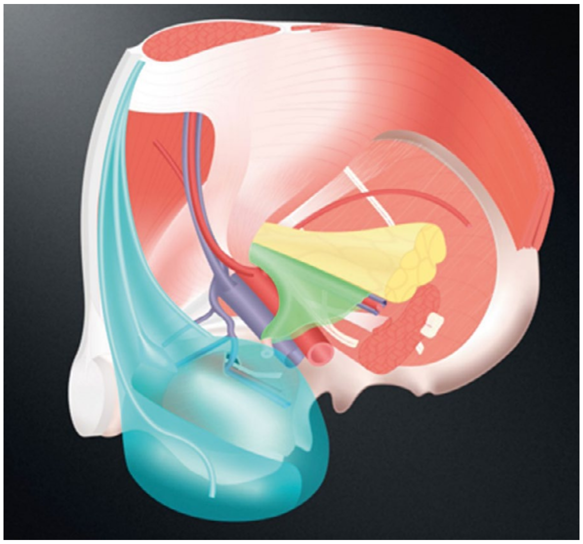

FIGURE 82.14 The umbilical-vesical fascia *(blue)* surrounds the bladder. Anterior to this fascia is the prevesical space of Retzius.

The Umbilical-Vesical Fascia and Associated Microfascia

The umbilical-vesical fascia is derived from embryonic structures. The median ligament, a remnant of the urachus, is at the midline. On each side are the medial ligaments, which correspond to the remnants of the umbilical arteries. These remnants may occasionally still contain patent vessels and bleed if divided. This fascia surrounds the bladder, and under it is the blood supply and autonomic innervation of the bladder. Anterior to this fascia is the prevesical space, or space of Retzius (Fig. 82.14).

The posterior transversalis fascia, or intermediate fascia, is an extension of the posterior rectus sheath and has a different level of development. The intermediate fascia divides the medial or parietal compartment from the lateral or visceral compartment. The careful division of the intermediate fascia is an essential aspect of the MI IHR to achieve a critical view of the myopectineal orifice.

MANAGEMENT OF INGUINAL HERNIAS

Diagnosis

A detailed history and clinical exam should be conducted to gather information about risk factors for hernia development, symptoms, and their impact on quality of life. A thorough surgical history should be obtained because this may have a significant impact on operative management. A history of extensive abdominal or pelvic surgery may preclude a MI preperitoneal approach. In the setting of recurrence after an open anterior approach, a posterior MI approach may be warranted. In contrast, a failed MI approach may warrant an open anterior approach. A surgeon must attempt to obtain all prior operative reports, particularly those of prior hernia repairs. This can provide invaluable information about distorted anatomy and previously placed implants, such as mesh or fixation devices.

Clinical examination alone is recommended for confirming the diagnosis of an evident groin hernia. Examinations should be performed in both the standing and supine positions. If no obvious groin bulge is visualized, a Valsalva maneuver may aid in the diagnosis. Small hernias may require direct palpation of the external inguinal ring for a bulge. One should be suspicious of a femoral hernia if a bulge is discovered below the inguinal ligament.

Ultrasound (US) is a useful adjunct in the setting of vague groin swelling or occult groin hernias. CT or dynamic MRI is useful when US is negative or nondiagnostic. Imaging may also be useful for cases of recurrence or extreme presentations, such as massive scrotal hernias.

Treatment

Nonoperative Management

Given the natural tendency for groin hernias to progress with time, the discovery of a symptomatic hernia typically warrants operative repair. However, patients with minimal or no symptoms present a challenge to clinicians because they must balance the risk of hernia-related complications and those associated with operative repair. Fitzgibbons and colleagues performed a prospective randomized trial of watchful waiting for males with asymptomatic or minimally symptomatic inguinal hernias. The study randomized over 700 males to either watchful waiting or open tension-free hernia repair. No deaths were attributed to the study at 2-year follow-up, and the risk of hernia incarceration in the watchful waiting group was extremely low at 0.3% of study participants. Nearly a quarter of those in the watchful waiting arm crossed over to the operative group as a result of pain interfering with activity.[5] A later report demonstrated that the crossover rate to the surgical group increased to 68% at 10 years, with almost 80% of males older than 65 years of age receiving surgical repair. Patients who had surgery later did not experience increased surgical site infections or recurrence rates compared with those assigned to early repair.[6] These studies demonstrate that watchful waiting is a safe option for patients with asymptomatic or minimally symptomatic inguinal hernias and that operative outcomes are no different from those undergoing immediate repair. It is important to note that these results should not be applied to females because they were not included in this study. In addition, femoral hernias were not included in these studies and typically warrant timely surgical repair, given their greater risk of strangulation than inguinal hernias. Patients opting for nonoperative management may have some symptomatic improvement with the use of a hernia truss.

Operative Management—Open Techniques

Anterior approaches. Anterior hernia repairs are the most common technique for inguinal hernias worldwide. Current best practices recommend tension-free repairs, which can be done in various ways. Older tissue-based repair methods are rarely used today, except in cases of contamination or concurrent bowel resection, where using a mesh prosthesis may not be advisable.

Certain technical aspects of the procedure are consistent across all anterior repairs. The open hernia repair procedure begins with a transverse or slightly curved incision made just above the inguinal ligament and approximately a fingerbreadth below the internal inguinal ring. Topographically, the internal inguinal ring is situated midway between the ASIS and the pubic tubercle on the same side. Dissection then proceeds through the subcutaneous tissues and Scarpa's fascia. The EO fascia and the external inguinal ring are first identified, after which the EO fascia is incised through the superficial inguinal ring to expose the inguinal canal. It is crucial to identify and carefully handle the ilioinguinal nerve, iliohypogastric nerve, and genital branch of the GF nerve to prevent inadvertent transection or entrapment. Awareness of nerve location is important to prevent damage because this is the main cause of postoperative chronic pain after inguinal hernia surgery. The spermatic cord is mobilized at the pubic tubercle using a combination of blunt and sharp dissection techniques. Improper mobilization, particularly laterally, can lead to confusion in identifying tissue planes and essential structures, potentially resulting in harm to the spermatic cord structures or disruption of the inguinal canal floor.

The cremaster muscle, a part of the mobilized spermatic cord, is separated parallel to its fibers from the underlying cord structures. The cremaster artery and vein, which join the cremaster muscle near the deep inguinal ring, can often be avoided but may need to be sacrificed. In the past, some surgeons advocated skeletonizing the spermatic cord. However, it is advisable to minimize disruption to the cremasteric fibers and vasculature to reduce the risk of injury to the genital branch of the GF nerve. With an indirect hernia, the hernia sac is situated deep to the cremaster muscle and anteromedial to the spermatic cord structures. Usually, spreading the cremaster muscle longitudinally is sufficient to expose an indirect sac. The hernia sac should be carefully separated from adjacent cord structures and dissected to the level of the internal inguinal ring. If the sac is large, it is opened and examined for visceral contents, although this step is unnecessary for small hernias. The sac can either be mobilized and placed within the preperitoneal space or ligated at the level of the internal ring, with any excess sac being excised. If dealing with a large hernia sac, electrocautery may be used for division to facilitate ligation. There is no need to remove the distal portion of the sac. For broad-based sacs, it may be more practical to reduce them into the peritoneal cavity rather than ligate them. Direct hernia sacs protrude through the floor of the inguinal canal medial to the epigastric vessels and can be reduced below the transversalis fascia before repair. This requires incising the weakened floor (transversalis fascia) to reveal the underlying preperitoneal fat, which can then be mobilized from the neck of the direct defect, and any other component of the direct hernia is reduced. Once the floor of the inguinal canal is opened, one should look for a femoral hernia, which, if present, will be found in the preperitoneal space medial to the femoral vein. After this exploration, the redundant transversalis fascia is excised, and the floor can often be reapproximated using a continuous absorbable suture. A cord lipoma, which is retroperitoneal fat that has herniated through the deep inguinal ring, should be suture-ligated and excised. Cord lipomas can serve as a mechanism for recurrence and can also be a persistent postoperative bulge felt by patients.

During the dissection of the hernia sac, one should take care to recognize the components of the hernia sac. A sliding hernia presents a unique challenge in managing the hernia sac. A *sliding hernia* is defined as a hernia in which part of the hernia sac comprises visceral peritoneum covering a retroperitoneal organ, typically the colon or bladder. In such cases, the grossly redundant portion of the sac should be excised, with care not to injure any viscera involved with the sac, and the peritoneal defect is then closed. The viscera and sac can then be reduced.

Tissue Repairs

Although the use of tissue repairs has significantly diminished because of their high recurrence rates, they still find relevance in specific clinical scenarios. Tissue repairs are indispensable when dealing with strangulated hernias necessitating bowel resection because the use of synthetic mesh prostheses is contraindicated. Several options are available for tissue repairs, including the IPT, Shouldice, Bassini, and McVay repairs.

The IPT repair is performed by approximating the transversus abdominis aponeurotic arch to the IPT using interrupted sutures (Fig. 82.15).

The repair begins at the pubic tubercle and extends laterally beyond the internal inguinal ring. It is worth noting that although this repair was initially described with a relaxing incision (as elaborated on later), many surgeons who employ this technique do not perform a relaxing incision as part of the procedure.

The Shouldice repair emphasizes a multilayer imbricated reconstruction of the posterior wall of the inguinal canal. It is considered the best tissue-based approach according to recent guidelines and expert consensus.[2] Although no studies exist comparing the learning curves of different nonmesh techniques, the Shouldice is not an easy technique to learn. At the Shouldice Hospital, surgeons are only considered qualified after 300 cases.[2] The repair is done using a continuous running suture technique. After completion of the dissection, the posterior wall of the inguinal canal is meticulously reconstructed by superimposing running suture lines, progressing from the deeper to more superficial layers. The initial suture line secures the transversus abdominis aponeurotic arch to the IPT. Subsequently, the IO and transversus abdominis muscles and

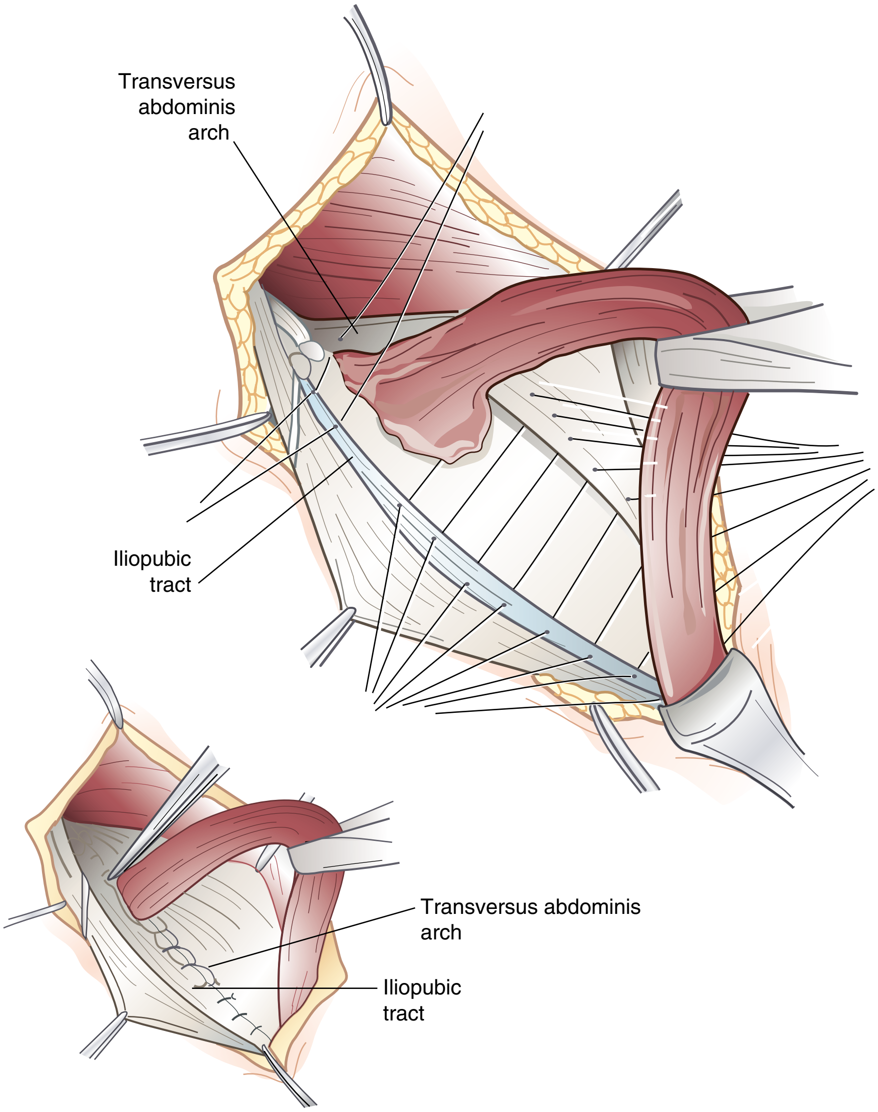

FIGURE 82.15 Iliopubic tract repair.

aponeuroses are sutured to the inguinal ligament. The Shouldice repair is known for its remarkably low recurrence rate and a high degree of patient satisfaction, particularly in highly selected patients.

The Bassini repair is performed by suturing the transversus abdominis and IO musculoaponeurotic arches, or the conjoint tendon when present, to the inguinal ligament. This once-popular technique represents the fundamental approach to nonanatomic hernia repairs and was the prevailing method employed before the emergence of tension-free repair methods.

The Cooper's ligament repair, often referred to as the *McVay repair,* has been a popular choice for addressing various types of groin hernias, including direct hernias, large indirect hernias, recurrent hernias, and femoral hernias. In this procedure, interrupted nonabsorbable sutures are used to approximate the edge of the transversus abdominis aponeurosis and Cooper's ligament. When the medial aspect of the femoral canal is reached, a transition suture is placed to incorporate Cooper's ligament and the IPT, making it effective for the repair of femoral hernias when present. Lateral to this transition stitch, the transversus abdominis aponeurosis is secured to the IPT. A key principle of this repair involves the use of a relaxing incision. This is performed by reflecting the EO aponeurosis cephalad and medial, which exposes the anterior rectus sheath. A curvilinear incision is then made, starting 1 cm above the pubic tubercle and extending along the anterior sheath toward its lateral border. This technique reduces tension on the suture line, resulting in decreased postoperative pain and a lower risk of hernia recurrence. The fascial defect created by this incision is covered by the body of the rectus muscle, preventing herniation at the site of the relaxing incision. The McVay repair is particularly well suited for addressing strangulated femoral hernias because it obliterates the femoral space without the need for mesh.

Other novel tissue-based approaches have been described in the literature. For example, the Desarda hernia repair technique focuses on reinforcing the inguinal canal while preserving the patient's native tissues. In this procedure, a strip of the patient's EO aponeurosis is used to reconstruct the weakened inguinal floor. These tissue-based hernia repair techniques serve as valuable options in specific clinical scenarios where mesh prostheses are not suitable. Each technique has its own set of indications and is chosen based on the unique characteristics of the patient and the hernia being treated.

Tension-Free Anterior Inguinal Hernia Repair

Tension-free repair has become the most common approach to IHR. Recognizing that tension is a primary contributor to hernia recurrence, modern hernia practices typically use a synthetic mesh prosthesis to bridge the hernia defect, a concept popularized by Lichtenstein. There are several options for mesh placement in anterior inguinal herniorrhaphy, including the Lichtenstein approach, plug and patch technique, and sandwich technique involving both anterior and preperitoneal mesh pieces. However, recent guidelines suggest that a flat piece of mesh is preferred over three-dimensional meshes.[7]

In the Lichtenstein repair (Fig. 82.16), a piece of prosthetic nonabsorbable mesh is customized to fit the inguinal canal, with a

slit cut into the distal lateral edge to accommodate the spermatic cord. Various preformed, commercially available prostheses are suitable for this purpose, or a surgeon can trim their own mesh construct. The periosteum overlying the pubic tubercle is exposed and dissected medially toward the midline of the pubis for at least 2 cm. Mesh fixation directly to the pubic tubercle is avoided to minimize the risk of chronic groin pain and osteitis. The inferolateral edge of the mesh is sutured to the shelving edge of the inguinal ligament, starting adjacent to the pubic tubercle but not into it, using a nonabsorbable suture. The medial aspect of the mesh generously overlaps the pubic tubercle by at least 2 cm. This suture is taken to a point lateral and superior to the internal inguinal ring and tied. Interrupted sutures are then placed to secure the superomedial aspect of the mesh to the conjoint tendon, with care to prevent injury or entrapment of the ilioinguinal and iliohypogastric nerves. The tails created by the slit are sutured together around the spermatic cord, forming a new internal inguinal ring. Special care is taken to safeguard the ilioinguinal nerve and genital branch of the GF nerve from entrapment, either by placing them with the cord structures as they pass through the newly fashioned internal inguinal ring or avoiding their enclosure in the repair.[8]

Posterior Approaches

An alternative tension-free mesh repair approach involves the preperitoneal placement of a self-expanding polypropylene patch.[9] A pocket is crafted within the preperitoneal space through gentle dissection, and a preformed mesh patch is introduced into the hernia defect. It expands to cover the direct, indirect, and femoral spaces and lies parallel to the inguinal ligament. This patch can remain in place without the need for suture fixation, although a tacking suture can be applied if deemed necessary. This technique requires a good understanding of preperitoneal anatomy.

The Rives-Stoppa repair method uses an infraumbilical midline incision to introduce a large mesh prosthesis into the preperitoneal space.[10] Blunt dissection is used to create an extraperitoneal space that extends into the space of Retzius, beyond the obturator foramen and posterolateral to the pelvic brim. This approach offers the advantage of evenly distributing natural intraabdominal pressure across a wide area, thereby ensuring the mesh remains appropriately positioned. The Rives-Stoppa technique is particularly valuable when managing large, recurrent, or bilateral inguinal hernias.

The open preperitoneal approach proves beneficial for repairing recurrent inguinal hernias, sliding hernias, femoral hernias, and select strangulated hernias.[11] It begins with a transverse skin incision created 2 cm above the internal inguinal ring and directed toward the medial border of the rectus sheath. The muscles of the anterior abdominal wall are incised transversely, and the preperitoneal space is then identified. For enhanced exposure, the anterior rectus sheath may be incised to enable medial retraction of the rectus muscle. Cephalad retraction of the preperitoneal tissues reveals the posterior inguinal wall and the hernia defect. Generally, there is no need to divide the inferior epigastric vessels because they are usually situated beneath the midportion of the posterior rectus sheath. This approach minimizes manipulation of the spermatic cord and reduces the risk of injury to the sensory nerves of the inguinal canal, a crucial consideration for hernias previously repaired through an anterior approach. In cases where the peritoneum is incised, it is sutured closed to prevent intraperitoneal contents from protruding into the operative field. Identification and suturing of the transversalis fascia and transversus abdominis aponeurosis to the IPT using permanent sutures is a key component of this approach. For femoral hernias addressed via this technique, closure of the femoral canal is accomplished by securing the repair to Cooper's ligament. The use of a mesh prosthesis is a common choice to obliterate the defect in the femoral canal, particularly for large hernias.

Operative Management—Minimally Invasive Techniques

The most used MI techniques for IHR are the transabdominal preperitoneal (TAPP), totally extraperitoneal (TEP), and enhanced-view totally extraperitoneal (eTEP) approaches. These are all approaches to preperitoneal IHR and may all be performed with traditional or robotic-assisted laparoscopic surgery. Regardless of the technique chosen, the critical view of the myopectineal orifice (CV of the MPO) should always be obtained to reduce complications and recurrence.[12]

The Critical View of the Myopectineal Orifice

The CV of the MPO was described to standardize the dissection performed during an MI IHR. The protocol to achieve this was developed based on the best available evidence that demonstrated fewer hernia recurrence and complications.[12] Obtaining the CV of the MPO is important to ensure a safe dissection with adequate mesh overlap of the MPO. It is important to note that all of the following steps must be performed to achieve the CV of the MPO, but not necessarily in the order described. The pubic tubercle must be identified and dissected past the midline, and the ipsilateral Cooper's ligament in relation to the hernia defect must be identified. For large direct inguinal hernias, the preperitoneal dissection should extend to the contralateral Cooper's ligament for adequate mesh overlap. The direct space must be identified by clearly visualizing Hesselbach's triangle and removing any adipose tissue within it that may obscure a hernia defect. Dissection in the space of Retzius must be performed such that there is at least 2 cm between Cooper's ligament and the bladder to facilitate flat placement of the inferomedial edge of the mesh. This is critical to prevent mesh dislodgment or folding (commonly referred to as mesh *clam-shelling*) with bladder distention. Dissection between the external iliac vein and Cooper's ligament should be performed to identify the femoral orifice and rule out a femoral hernia. The indirect sac and peritoneum must be dissected off the gonadal vessels and vas deferens. Parietalization of these structures until they lie flat ensures proper placement of the inferior border of the mesh. This step is often not completed because of fear of injuring the iliac vessels or if there is a limited surgical field. Once the psoas muscle and iliac vessels are visualized, traction of the hernia sac and peritoneum should not trigger any movement of the cord elements. If there is movement of the cord elements, further dissection should be performed. Cord lipomas must be identified and reduced. These are usually lateral to the cord elements, unlike lymph nodes, which are typically medial. Most cord lipomas can be reduced such that they are placed above the mesh; however, large lipomas may require excision. The preperitoneal space should be carried laterally beyond the ASIS such that the peritoneal reflection will be inferior to the mesh. Once adequate dissection is achieved, mesh is placed. Any fixation used should be placed well above an imaginary line between the ASIS and internal inguinal ring to avoid recurrence and nerve injury. The mesh should be at least 10 cm by 15 cm, although a larger mesh may be needed for adequate MPO coverage. The mesh should adapt to the contour of the space and cord elements without significant memory and should lie flat, without creases or folds. It is not recommended to split the mesh for pass-through of the cord elements. Deflation of the space should be performed with visualization to ensure the mesh does not fold. If this occurs, the mesh may need to be repositioned, or further preperitoneal dissection may need to be performed to prevent mesh migration during deflation. Please refer to Video 82.1 for further details.

Transabdominal Preperitoneal Inguinal Hernia Repair

The most common MI inguinal hernia approach is a TAPP. The technique of abdominal access and establishment of pneumoperitoneum is performed at the discretion of the surgeon. A camera port is typically placed in the midline at least 15 cm from the pubis to allow ample working room. Two additional working ports are placed lateral to the camera port on each side of the abdomen. A peritoneal flap is initiated by incising the peritoneum medially at a distance 4 to 6 cm superior to the hernia defect and carrying this incision laterally to the ASIS. Dissection then continues to achieve a critical view of the myopectineal orifice, as described earlier. Once the mesh is placed, the peritoneal flap should be closed to exclude the mesh from the peritoneal cavity, avoid dislodgement of the mesh, and prevent visceral adhesions. Please refer to Video 82.2 for further details.

Total Extraperitoneal Inguinal Hernia Repair

The total extraperitoneal repair (TEP) is an MI inguinal hernia mesh repair technique that allows access to the preperitoneal space by an anterior approach without entering the peritoneal cavity. It was first introduced in 1993 by McKernan and colleagues.[13] Patients are typically positioned supine with their arms tucked. The TEP procedure begins with retrorectus access. A 1- to 2-cm infraumbilical incision is made, and the anterior rectus sheath is identified. Stay sutures are placed, and the anterior rectus sheath is incised, revealing the underlying rectus abdominis muscle. The muscle fibers are then spread to reveal the posterior rectus sheath. This retromuscular/preperitoneal space can then be established from the incision down to the level of the pubic tubercle. The space is widened with assistance of different techniques, such as balloon-mediated separation or manual endoscopic-assisted dissection (Fig. 82.17).

Once the space is developed, insufflation is established via a Hasson cannula. Two additional 5-mm ports are inserted along the midline inferiorly or laterally based on surgeon preference.

Dissection to achieve the critical view of the myopectineal orifice is performed. Once the mesh is placed, the preperitoneal space is deflated under direct visualization to ensure stable positioning of the mesh.

Enhanced-View Totally Extraperitoneal Inguinal Hernia Repair

The enhanced-view totally extraperitoneal (eTEP) approach to IHR was described in 2009 as an evolution of the TEP approach. The goal of eTEP was to improve the operative field to facilitate an

extraperitoneal approach.[14] The port placement between the pubis and the umbilicus in the TEP approach can pose ergonomic challenges to the surgeon. With division of either the medial or lateral aspect of the arcuate line, the preperitoneal space can be significantly increased for dynamic port placement.

During an extraperitoneal approach, especially TEP, it is critical to avoid creating holes in the peritoneum because CO_2 will otherwise escape from the preperitoneal space into the peritoneal cavity and significantly decrease the surgeon's working room. Breaches in the peritoneum should be controlled with either clips or suture. Another intraperitoneal port may be placed to vent the peritoneum. However, if the preperitoneal space is unable to be maintained, conversion to a transabdominal approach may be warranted. In addition, unrecognized large peritoneal defects increase the risk of an intraparietal hernia in which herniation of bowel contents occurs between the layers of the abdominal wall. This can present as early bowel obstruction. Please refer to Video 82.3 for further details.

Selection of Operative Technique

Selecting a surgical technique for IHR should be tailored to the patient and hernia characteristics, the surgeon's experience and preferences, and the resources available.[2] Surgeons desiring to offer comprehensive treatment for inguinal hernia should be proficient in both anterior and posterior approaches, mesh and nonmesh repairs, and open and MI techniques.

Although we acknowledge the wide array of surgical techniques for IHR and variety of practice patterns, the authors adhere to the following recommendations. Contaminated cases such as bowel necrosis secondary to a strangulated hernia typically preclude mesh repair, and a tissue-based repair should be chosen. Mesh-based repair is recommended for adult inguinal hernias, and flat-mesh Lichtenstein technique is favored over three-dimensional implants. For nonmesh repairs, a Shouldice technique is recommended. In recent times, there has been a shift toward MI techniques, which have demonstrated some advantages over open techniques, such as decreased postoperative and chronic pain and a faster return to normal activity.[15,16] Recent guidelines suggest that an MI (TEP or TAPP) technique is preferred for bilateral inguinal hernias and femoral hernias. This approach is also recommended for females, given their higher incidence of femoral hernias. Although open repairs can be associated with excellent outcomes in experienced hands, there is increasing acceptance of MI techniques as the favored approach for primary unilateral groin hernias in males. A posterior repair is recommended after a failed anterior repair, and vice versa.[2,7] For example, a recurrence after an open Lichtenstein repair could be adequately managed with MI TAPP. Although there are no absolute contraindications to an MI approach other than inability to tolerate general anesthesia, patients with significant surgical history, particularly in the lower abdomen, may be best managed with an anterior approach, given the likelihood of adhesions or difficult preperitoneal dissection.

COMMON POSTOPERATIVE COMPLICATIONS

Seromas and Hematomas

Perioperative complications are relatively common. The overall complication rate is estimated to range from 5% to 10%. Seromas and hematomas result from fluid or blood collecting in the dead space that remains after repair. A recent prospective randomized controlled trial (RCT) comparing open Lichtenstein repair and laparoscopic TEP showed an increased seroma risk in TEP of 7.9% versus 3.4%.[17] At the end of the procedure, some surgeons opt to leave a drain in the preperitoneal space. A study from 2023 showed that closed-suction drainage led to decreased scrotal edema, seroma, and urinary retention at 3 months.[18] The benefits of routine drain placement should be balanced with the possible risk of a foreign body adjacent to the mesh. In our practice, drains are not routinely used and are reserved for complex or large inguinal hernias. Most small seromas and hematomas can be successfully managed conservatively with observation. Seromas that persist with time or cause significant discomfort may be aspirated. Rarely, seromas may need to be surgically excised if refractory to percutaneous drainage. Large hematomas should be evacuated to decrease clot burden because they can cause significant discomfort and take a long period of time to resolve on their own. This can be done with an MI or open approach, depending on the location of the hematoma. Acute postoperative hematoma formation with concerns of active bleeding or hemodynamic changes should be urgently explored in the operating room.

Surgical Site Infection

Surgical site infections are characterized as superficial, deep, or involving organ space. A recent study using the National Surgical Quality Improvement Program database found an infection rate of 0.4% in a cohort of unilateral, initial open hernia repairs. Like other surgical site infections, this study found a two-times-greater risk for surgical site infections in those with diabetes, body mass index $\geq 35\ \text{kg/m}^2$, and current smoking.[19] In a recent prospective RCT comparing open Lichtenstein repair and laparoscopic TEP, the open repair had a higher infection rate of 4.6% compared with TEP at 2.2%.[17]

Prophylactic antibiotics have not been shown to prevent wound infection in low-risk environments; however, they may provide benefit in high-risk environments. A Cochrane review from 2020 showed that antibiotic prophylaxis in adults undergoing elective open inguinal or femoral hernia repairs does not result in decreased postoperative wound infection.[20] Thus, published guidelines recommend antibiotic prophylaxis only in high-risk environments.[7] Postoperative superficial skin infections are often managed conservatively with administration of antibiotics or opening of incisions with fluctuance or drainage. If initial conservative treatment is unsuccessful, one must consider the presence of a deep infection, which could involve mesh. In those cases, surgical exploration with debridement may be indicated.

Mesh Infection

Mesh infection is a devastating complication that is estimated to occur in 1% to 4% of abdominal hernia repairs. Mesh infections present with indolent symptoms and clinical findings such as swelling, pain, draining sinus tracts, or masses. They often present without obvious inflammation of surrounding skin. The diagnosis is usually based on clinical presentation; however, imaging such as US and CT scans can aid in the diagnosis.

With inguinal mesh infection, surgical removal is almost always warranted. Before surgical removal, conservative treatment such as local wound care can be trialed. Subsequent mesh removal can be completed at least 3 months after onset of symptoms. The additional time allows the unaffected part of the mesh to become further incorporated into the surrounding tissue. Meanwhile, the infected part of the mesh separates secondary to the purulent exudate, allowing for easier mesh removal. Typically, the mesh is removed with the same surgical technique that was used for placement, such that TAPP or

TEP hernia repairs have mesh removed laparoscopically. However, if an open repair is complicated by peritoneum penetration or presence of a sinus, then surgeons may consider a laparoscopic approach to visualize the abdominal cavity. Studies suggest that complete removal of mesh results in less infection recurrence compared with partial mesh removal.[21] After explantation of the infected mesh, replacement with another synthetic mesh in the setting of infection is contraindicated. Hernia recurrence after removal of an infected mesh is not common because there is typically an inflammatory reaction that provides strength for the repair.

Postoperative Urinary Retention

Postoperative urinary retention (POUR) has a highly variable incidence of 0.4% to 41.6%. A recent large international multicenter prospective cohort study was developed to identify related risk factors. In the study's cohort of 4151 adults across 32 countries, the incidence was 5.8% in males, 3.0% in females, and 9.5% of male patients ≥65 years old.[22] The study found multiple risk factors, several of which are modifiable, including anticholinergic medication, history of prior urinary retention, constipation, involvement of bladder within hernia, temporary intraoperative urethral catheterization, longer operative times, and increasing age. Treatment for POUR is conservative. Most patients are managed with indwelling ureteral catheterization. Less commonly, patients undergo intermittent catheterization or, in even rarer circumstances, suprapubic catheterization. Of 30-day readmissions in the RETAINER I trial, 51.8% were a result of POUR, accounting for the majority of cases. Unplanned admissions and readmissions from POUR still occurred relatively infrequently, occurring in 1% to 3% of patients. Between 12% and 27% of patients admitted were discharged with indwelling catheters. By 30-day follow-up, most (65%) had successfully passed a void trial and no longer required catheterization. Results of this study suggest that POUR is not an uncommon complication and that although most patients can spontaneously void by 30 days postoperatively, many required catheterization, which can be uncomfortable and traumatic.

Additional studies have compared neuromuscular blockade agents and association with POUR. The use of the newer cyclodextrin agent sugammadex relative to the traditional anticholinesterase group was associated with reduced 30-day POUR by 66% overall. This was also significant in subsets of groups, including open, MI, unilateral, and bilateral repairs.[23] Additionally, research has shown an independent association between perioperative administration of dexamethasone and decreased urinary retention.[24]

Hernia Recurrences

Inguinal hernia recurrences are estimated to occur in 5% to 10% of patients. Mesh repairs are the standard of care in most cases and have been found to substantially reduce recurrence by 60%. Risks for recurrence include any condition that results in chronically elevated intraabdominal pressure (e.g., chronic cough, ascites, benign prostatic hyperplasia) or impairs wound healing, such as connective tissue disorders, tobacco use, and infection. There is also a higher frequency of recurrences with recurrent hernia repairs. Additionally, recurrence is seen more often after repair of direct hernias rather than indirect hernias that originate at the deep ring. If a recurrence occurs, the typical approach for repair of the recurrence is usually from the opposite side of the index procedure to prevent operating in the failed surgical plane. If an anterior repair, such as the Lichtenstein repair, fails, an MI posterior approach is typically used. Similarly, if a posterior repair fails, an anterior repair is recommended.[25]

Chronic Groin Pain

Chronic pain is estimated to affect approximately 10% of patients after IHRs and is defined as postoperative pain lasting over 3 months. Of these patients, 2% to 4% report pain that interferes with daily activity.[26] With mild symptoms, patients suffer a decrease in quality of life, whereas those with more severe symptoms may have an impaired ability to work or suffer from psychological conditions such as depression. Some have suggested that a waiting period of 3 months after hernia surgery is appropriate before making the diagnosis of chronic pain. This time frame is appropriate, except in the setting of severe new-onset postoperative pain that was not present before the hernia repair. This presentation suggests nerve entrapment, and prompt surgical reexploration should be performed to identify and treat the source of pain.

There is a wide array of causes of chronic pain after IHR, which will be discussed later in this chapter. The workup of chronic pain is very important, and patients should be referred to experts who are experienced in treating postoperative chronic pain. The ilioinguinal nerve, which provides sensation to skin of the groin, inner thigh, upper part of the scrotum, and root of the penis, has been implicated as a contributor to postoperative pain. This nerve is typically at risk of injury during open repairs because it is not exposed during MI posterior repairs, such as branches of the GF and lateral femoral cutaneous nerves. Although there have been studies advocating prophylactic ilioinguinal neurectomy, it is our practice to preserve this nerve if possible.[27,28] It is advised against dissecting these nerves from their muscular beds or placing them behind retractors to maintain the surgical field. Maneuvers such as these increase the chance of nerve injury. However, most experts agree that the ilioinguinal nerve and/or the iliohypogastric nerve should be resected if they are injured or interfere with mesh positioning, given the risk of nerve entrapment.[25]

Chronic pain has also been associated with penetrating mesh fixation. An RCT from 2023 compared mesh fixation with tacks versus no fixation and found similar recurrence rates with less acute and chronic pain without fixation.[29] Other independent risk factors for chronic postoperative pain include bilateral IHR, preoperative pain, preoperative anxiety, and relatively high intensity of acute pain for 1 week postoperatively.[30] For MI posterior approaches, the nerves at risk of injury are the lateral femoral cutaneous and both the genital and femoral branches of the GF nerve. Aggressive dissection and mesh fixation should be avoided below the IPT to avoid injury to these nerves. Chronic pain after IHR is initially managed conservatively with nonsteroidal antiinflammatory medications and analgesics. Local nerve blocks can also be pursued and, if successful, suggest that the patient may benefit from surgical exploration with neurectomy or mesh removal if the patient's pain recurs once the block wears off. The workup and treatment of chronic pain patients can be very time consuming and stressful for both the patient and the surgeon, highlighting the importance of multidisciplinary management.

SPECIAL CONSIDERATIONS

Sliding Hernias

A sliding hernia is one in which a retroperitoneal organ "slides" down posteriorly and herniates because it is part of the hernia sac. A recent study of the National Danish Hernia Database estimated the incidence of sliding hernias to be 13.5%. The risk of sliding inguinal hernias increases with age. Common involved organs include the cecum, ascending colon, appendix on the right side, and sigmoid colon on the left side. These hernias may also involve the uterus, fallopian tubes, ovaries, ureters, and bladder on either side. If a sliding hernia is present, the repair must be modified such that the hernia sac is opened with care not to injure the involved organ. Intraperitoneal structures should then be identified and reduced. Redundant sac management will differ depending on the chosen technique, either open or laparoscopic. In open repairs, the excess sac should be excised and the peritoneal defect closed. In laparoscopic repair, after complete reduction of contents, the excess sac should be separated from the spermatic cord and is often reduced. If the wall of the sac appears thick, care should be taken to confirm this is not, in fact, the wall of a retroperitoneal organ itself that is involved in the hernia. The presence of a sliding hernia likely does not result in a higher risk of postoperative complications, although there are few studies that report increased seroma, hematoma, and urinary retention. In terms of recurrence, there is a higher risk of recurrence, especially after open Lichtenstein repairs.[31]

Scrotal Hernias/Loss of Domain

Giant inguinal hernias, or "scrotal abdomen," are classified as those that extend past the midpoint of the inner thigh in the standing position. They are uncommon and develop in those who neglect their symptoms or do not have access to surgical services. Risk factors for massive scrotal hernias are similar to those for recurrence, including conditions that increase intraabdominal pressure or impair wound healing. In cases of large scrotal hernias or loss of domain, open repairs are typically preferred. Preoperatively, efforts should be made to decrease the bulk of contents in the hernia sac by altering the patient's diet to reduce intraluminal intestinal contents or by intraoperatively completing simultaneous intestinal resection. Repair of these large hernias can be morbid secondary to the rise in intraabdominal pressure that reduction causes, thereby decreasing diaphragmatic compliance. This postoperative rise in pressure can result in respiratory failure, pneumonia, wound dehiscence, or hernia recurrence. As a result, careful preoperative patient selection should be performed, including those with adequate pulmonary function. Adjuncts that can assist in decreasing intraabdominal pressure include Botox and progressive pneumoperitoneum.

INGUINODYNIA (GROIN PAIN) AS A CHIEF COMPLAINT

Workup

When investigating the source of chronic groin pain, a comprehensive history, physical exam, and review of prior radiographic studies must be performed. The SPORT acronym developed by the International Hernia Collaboration is a helpful framework for pursuing a thorough workup in these patients (Box 82.1).

When providing pain history, the patient should provide details such as the onset of the pain, quality of pain, radiation patterns, and prior trials of medical therapies. If operative reports are available, it is helpful to note the type of mesh and which nerves, if any, were identified. It is important to investigate whether there were any complications intraoperatively or perioperatively. To document the starting event, the full pain history must include the following:

- Where is it located, exactly?
- When did it start (how, why)?
- Constant or intermittent?
- What makes it worse or better (medications/injections)?
- Does it radiate, and if so, to where?
- Severity (vas score 1–10)
- Mental health history (posttraumatic stress disorder [PTSD], depression, anxiety, etc.)

The differential diagnosis of chronic groin pain is vast:

- Mesh, meshoma, sutures, or tacks
- Trapped nerve (iatrogenic or anterior cutaneous nerve entrapment syndrome [ACNES]), with or without fascial tear
- Hernias (direct, femoral, obturator, or indirect), which includes occult (hidden) and recurrent hernias (lump not required)
- Lipoma (usually retained cord lipomas)
- Endometrioma, round ligament pain
- Osteitis, rectus sheath tear, aponeurotic plate avulsion, adductor tear, other
- Intraabdominal pathology (e.g., adhesions or appendicitis)
- Back/spine (sacroiliac joint dysfunction or thoracolumbar syndrome)
- Hip joint (femoral-acetabular impingement or labral tear)
- "Psychosomatic," "pain-body," or other previous unprocessed trauma or mental health conditions (conscious or unconscious)

A distinction also needs to be made between neuropathic and nociceptive pain. Pain mapping in the office can aid in this differentiation. The physician can simply mark a "+" along all the areas where the patient endorses pain and a "0" where there is none. Typically, a large area aligns with neuropathic pain, whereas a narrow area is more indicative of nociceptive pain (Figs. 82.18 and 82.19).

Relevant radiographic studies include dynamic sonograms, CT scans with radiopaque markers, MRI with radiopaque markers, and diagnostic laparoscopy. Dynamic sonograms are completed with the US probe placed at the point of pain with the patient

standing still and performing the Valsalva maneuver. These tests are relatively inexpensive and can effectively evaluate for a hernia or recurrence but depend on a good technician and experienced interpreter. Some hernias can be missed in inexperienced hands. If US is proven to be nondiagnostic, CT or MRI with a radiopaque marker at the point of pain are the next imaging modalities of choice.

Treatment

The treatment of inguinodynia, much like the treatment of other forms of chronic pain, is generally approached in a stepwise and tailored fashion. Noninvasive techniques such as rest, ice and heat, and over-the-counter antiinflammatory medication can provide relief to many patients, especially those with a clear inciting event for their pain, such as a sports injury or recent surgery. Certainly, a referral to a pain specialist to aid in the nonoperative workup and treatment is always helpful.

If conservative therapy does not manage the patient's pain, more aggressive pain management techniques are available. Patients with neuropathic pain may benefit from gamma-aminobutyric acid (GABA) modulators such as gabapentin. However, it is important to avoid prescribing narcotic pain medications before other methods have been exhausted. Inguinal or other nerve blocks administered by a surgeon or an interventional pain specialist can provide relief, but patients may need repeated nerve blocks to maintain pain control. If patients respond to the block but require repeated interventions, a surgical neurectomy may offer benefit. Adjunctive treatment options such as physical therapy and massage are available for patients who have a sports-related injury or other musculoskeletal complaint.

The surgical treatment for chronic pain will depend on the history and the etiology of pain, and sometimes multiple surgical interventions may be necessary. Despite surgical intervention, the pain-free success rate will approach around 70%, with the remaining 30% having some level of persistent chronic pain or discomfort.

Surgical Evaluation and Mesh Explantation

Surgical diagnosis and therapy with diagnostic laparoscopy can be helpful in patients who have failed nonsurgical management, particularly those who have a history of surgery associated with the onset of their groin pain. Laparoscopy can identify adhesions, recurrent or occult hernias, and issues with mesh placement or fixation that may be contributing to a patient's pain. It is helpful to perform pain mapping preoperatively and postoperatively to assess the patient's response to the intervention.

During the procedure, the preperitoneal space can be explored to evaluate the cord structures and nerves that may be injured or inflamed. The triple neurectomy, performed through an open approach and targeting the ilioinguinal, iliohypogastric, and GF nerves, has proven to be one of the most effective options for patients with persistent postoperative neuropathic groin pain. If a hernia is present, the goal of the operation is to provide a durable hernia repair. If there is no hernia, the goal is to eliminate any adhesions from the groin and clear the groin of all foreign materials, which may include mesh and its fixation materials, thereby freeing up the cord structures and nerves.

If prior mesh is thought to be the source of pain, the approach in which the mesh was previously implanted (e.g., open anterior approach) should be used to remove it. Although mesh explantation alone or with neurectomy can provide improvement in foreign body sensation and neuropathic pain, approximately a third of patients will not have resolution of their symptoms. Thus, although mesh removal is a viable surgical option, it is not always the cure for chronic pain after a hernia repair.

Referral to a cognitive or behavioral therapist may provide benefit in some patients with chronic pain. Mental health can play a role in the onset of pain, and mental health issues can develop during the months or years of patients experiencing pain without being able to obtain an accurate diagnosis. In these situations, some patients may feel neglected. Posttraumatic stress, anxiety, depression, and suicidal ideation have been reported during the workup of chronic pain. It is important to determine if there are ongoing mental health issues or ruminations during the evaluation and treatment of chronic pain patients, and findings should be well documented.

Sports Hernias and Athletic Pubalgia

A sports hernia, otherwise known as *athletic pubalgia,* is a groin pain syndrome that typically involves the deep muscular layers of the abdominal wall and tendons as they interact with the bony pelvis and inguinal ligament. It typically affects athletes, especially those participating in high-impact sports (e.g., ice hockey, rugby, soccer, American football) that put strain on musculotendinous structures of the inguinal region. The pubic tubercle is the site of insertion of the rectus abdominis, the conjoint tendon, the pubic symphysis, the adductor longus, and the inguinal ligament. The characteristic sports hernia pain typically exists around the pubic tubercle and may extend to or be more significant at the point of insertion of the adductor longus tendon on the pubic bone or above the insertion point of the rectus abdominis. Pain can also be at the inguinal ligament or directly at the pubic symphysis. Symptoms typically worsen with sprinting or lateral or twisting movements. Unlike typical groin hernias, sports hernias do not present with a bulge.

On physical exam, there is usually point tenderness of the external ring, which may also be dilated. The patient may also have point tenderness present at the pubic tubercle where the conjoint tendon meets. Another helpful physical exam maneuver involves putting the patient in a "frog leg" position (supine, knees bent, heels touching) to assess for pain with forced adduction against the examiner. It is important to distinguish this pathology from an adductor muscle injury because muscle injury alone is best managed with physical therapy. MRI is the diagnostic imaging study of choice to help differentiate sports hernia pain from hip joint–specific pathology. It may be used to diagnose inflammation of one or both tendons of the rectus abdominis or adductor longus muscle near their insertion sites. In severe cases, these tendons may also be avulsed and cause fracture of the pubic bone. MRI may also show bone marrow edema within the pubic bone that results from chronic strain at the tendon insertion sites. US with Valsalva is helpful to assess the inguinal canal and rule out inguinal hernias.

Initial management for sports hernias is conservative and includes applying ice packs, typically for around 10 minutes three to four times per day, administration of nonsteroidal antiinflammatory medications, rest, and subsequent rehabilitation once symptoms subside. Surgical treatment often follows when initial conservative management fails. The aim of surgical intervention is to reduce tension and torque on the pubic joint and decompress the inguinal sensory nerves. This is often performed with suture or mesh reinforcement. Studies have demonstrated that physical therapy has overall similar outcomes to surgery; however, these patients are often athletes eager to return to their sports and are not willing to wait.[32] The standard repair is a laparoscopic preperitoneal or open anterior repair with synthetic mesh. The open technique has the advantage of better identifying specific abnormalities responsible for pain and more precise anatomy given exposure. The outcomes for laparoscopic and open approaches were similar in prior RCTs; however, patients had less pain in the first month and sooner return to activity after laparoscopic compared with open repairs.[33] Similar to IHRs, these MI repairs can be performed via a TAPP or TEP approach.

An open repair begins with an incision slightly more caudal than in typical open IHRs to allow visualization of insertion points of the lower rectus and adductor longus tendons on pubic bone. From this point, there are various repair techniques that can be used to recognize anatomy and help correct weaknesses in the inguinal floor. These can be performed with or without mesh. Mesh can decrease tension on repair; however, it can result in mesh infection or related pain. These repairs can also be performed at the same time as adductor longus tenotomy, which results in a change in the pulling vector on the pubic bone. The goal of an adductor longus tenotomy is to relieve pressure on the adductor compartment and potentially decompress the obturator nerve. Overall, surgical treatment via laparoscopic and open repairs is successful in the short term, and most athletes can return to sports within 3 months.[33] Complications from repairs are uncommon. Postoperative physical therapy is recommended.

ESOPHAGEAL PHYSIOLOGY

Swallowing

The esophagus has a peculiar physiology. It is an organ of the digestive system without digestive, absorptive, endocrine, or exocrine functions and neglectable mucus production. Apart from peculiar, it is also complex. The esophagus has to propel food down from the pharynx to the stomach, even against gravity and irrespective of the bolus consistency, at the same time that it protects the airway from aspiration and itself from gastroesophageal reflux. For these purposes the esophagus is limited by two sphincters (the upper esophageal sphincter [UES] and the lower esophageal sphincter [LES]) and complexly innervated centrally by extrinsic sympathetic and parasympathetic nerves and peripherally by the enteric nervous system mediated by the vagus nerve and spinal nerves in a dual innervation.[1]

Peristaltic contraction results from the sequential activation of motor units innervating an aboral progression of esophageal muscle segments.[2] This will generate appropriate force and coordination for peristalsis. Opportune relaxation of the sphincters also occurs.

Antireflux Mechanism: Pathophysiology of Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) occurs because of an imbalance between the transdiaphragmatic pressure gradient and the valve mechanism at the level of the esophagogastric junction (EGJ)[3–5] (Fig. 83.1). Thoracic pressure is negative because of the inflation of the lungs generating a vacuum force. This tends to suck gastric contents upward. Abdominal pressure is positive because of abdominal compression or abdominal wall muscle contraction forcing gastric contents upward. Both pressures generate a positive pressure gradient. GERD does not occur thanks to a complex valvular mechanism at the level of the EGJ.

The valve mechanism at the level of the EGJ is composed of the following components:

1. *Lower esophageal sphincter*

   A 3- to 4-cm-long smooth muscle makes up the LES. It creates a sustained high-pressure zone between the esophagus and the stomach. A proper total, intraabdominal, and resting pressure are requirements for an effective LES. The majority of patients with GERD have a defective LES, but a large proportion have a normal LES pressure.[6,7] The LES pressure being overridden by a higher transdiaphragmatic pressure gradient explains this apparent contradiction.[8,9] Additionally, excessive transient LES relaxations (TLESRs) could be a factor.
2. *Diaphragm*

   The gastroesophageal barrier has an extrinsic component composed of the diaphragmatic crus. It puts additional pressure on the LES by pinching the esophagus's lower portion at the EGJ level during increased abdominal pressure through diaphragmatic contraction.

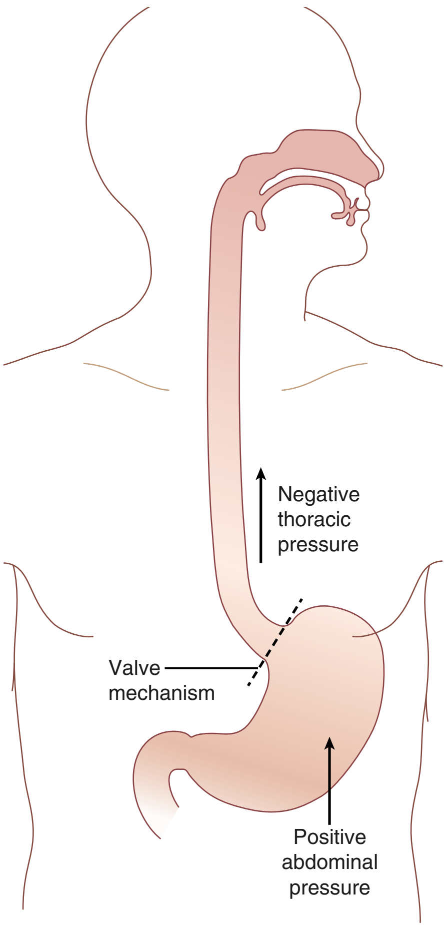

FIGURE 83.1 Gastroesophageal reflux disease pathophysiology is based on a balance between the transdiaphragmatic pressure gradient and the valve mechanism at the level of the esophagogastric junction.

3. *Angle of His*
   The angle of His refers to the acute angle created by the esophagus and gastric fundus. The distance between the gastric fundus, where food is stored, and the EGJ increases with increasing angle, acting as a barrier to the rise of the refluxate.[10,11]
4. *Gubaroff valve*
   Gubaroff valves consist of a thickening of the esophageal mucosa at the EGJ acting as a cushion keeping the area closed.[3]
5. *Intraabdominal portion of the esophagus*
   Because the abdominal pressure has the effect of collapsing the esophageal wall, the presence of an intraabdominal portion of the esophagus contributes to the valve mechanism.[12]

GERD will occur in the following scenarios when there is an imbalance between the transdiaphragmatic pressure gradient and the valve mechanism.

1. *Increased abdominal pressure*
   The clinical scenario where there is an increased abdominal pressure leading to GERD is in the setting of obesity, especially in males and females with central (opposed to peripheral) fat distribution.[13] It may occur also during pregnancy, in athletes with excessive abdominal training, and other situations.
2. *Decreased thoracic pressure*
   Decreased thoracic pressure related to an increased respiratory effort and consequently more negative thoracic pressure may occur in patients with obstructive pulmonary diseases or even professional glass blowers or singers.[14,15]
3. *Defective valve*
   Hiatal hernias are the most common reason for a defective EGJ valve because they disrupt most of the natural antireflux mechanisms. There is a lack of intraabdominal esophageal length that is now in the mediastinal position, obtuseness of the angle of His shortening the path from the gastric fundus to the esophagus, pressurization of the herniated gastric pouch, enlargement of the hiatus, and the fact that the diaphragm pinches the stomach rather than the esophagus. TLESR is also more frequent in patients with hiatal hernias[16] (Fig. 83.2).

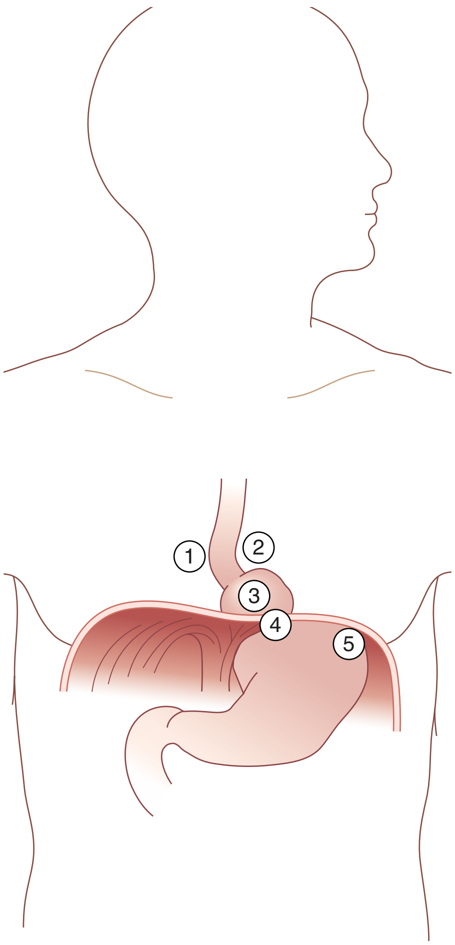

FIGURE 83.2 Disruption of natural antireflux mechanisms by a hiatal hernia. *(1)* Absence of intraabdominal esophagus length; *(2)* obtuseness of the angle of His; *(3)* lower esophageal sphincter in a negative pressure environment; *(4)* pressurization of the herniated stomach; *(5)* diaphragm does not pinch the lower esophageal sphincter.

ESOPHAGEAL FUNCTION TESTS

Esophageal Manometry

Esophageal manometry is performed through a transnasal catheter that is positioned with the tip in the stomach. The test is done after fasting, and sedation is not possible because the patient's collaboration is necessary, and esophageal function may be compromised by the action of the drugs. Drugs that may affect motility must be stopped opportunely. The test consists of a static phase

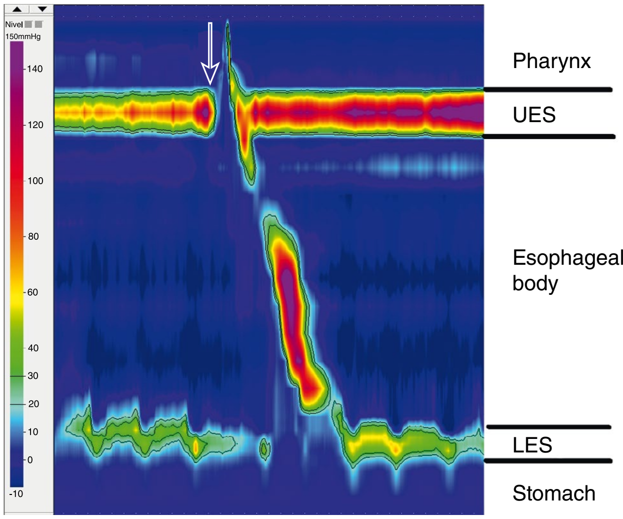

FIGURE 83.3 Normal esophageal manometry. One deglutition is shown *(arrow)*. Esophageal contraction pressure is translated in a code of colors *(left)*. *LES,* Lower esophageal sphincter; *UES,* upper esophageal sphincter.

to measure the sphincters' basal pressures and length followed by 10 swallows of water (dynamic phase) to evaluate sphincter relaxation and peristalsis. There are some provocative tests that can be added, but their real clinical significance is yet to be proven.[17] The test is able to evaluate pharyngeal contraction, UES basal pressure and relaxation coordination with pharyngeal contraction, esophageal body peristalsis, and basal pressure and relaxation of the LES (Fig. 83.3). Indications for esophageal manometry are shown in Table 83.1.[18]

The LES must be located using esophageal manometry in order to accurately determine the position of the pH monitoring catheter because other approaches are inaccurate. Esophageal manometry is useful to diagnose primary esophageal motility disorders (PEMDs) or the esophagus' involvement in systemic diseases (Table 83.2),[19,20] such as in patients with dysphagia or connective tissue diseases. Before esophageal operations at the EGJ, it is particularly crucial. Some believe that esophageal manometry findings may guide the type of antireflux operation, but it provides, nonetheless, a baseline comparison in case of unsuccessful outcomes. It may also classify achalasia according to the Chicago classification. It must be kept in mind that esophageal manometry cannot diagnose GERD. A normal LES does not rule out GERD because an abnormal transdiaphragmatic pressure gradient may overcome it, and an abnormal LES is not synonymous with GERD because other natural antireflux mechanisms may compensate for it. (see Table 83.2). Esophageal manometry interpretation is currently mostly guided by the Chicago classification.[21]

TABLE 83.1 Indications for Esophageal Manometry

- pH monitoring beforehand to determine the position of the catheter
- Evaluation of dysphagia
- Diagnosis of primary esophageal motility disorders
- Diagnosis of esophageal involvement in systemic diseases
- Determination of esophageal motility before antireflux surgery
- Evaluation of symptomatic patients after esophageal surgery

TABLE 83.2 Systemic Diseases That May Affect Esophageal Motility

Connective Tissue Diseases
Scleroderma
Raynaud disease and phenomena
Mixed connective tissue disorder
Sjögren syndrome
Rheumatoid arthritis
Systemic lupus erythematosus
Polymyositis, dermatomyositis

PD5-inhibitors
Antiparasitic agents

PD5-inhibitors, Phosphodiesterase type 5 inhibitors.

Lower Esophageal Sphincter and Esophagogastric Junction

Esophageal manometry is able to measure LES basal (resting) pressure. It will also define a hypotensive or normal LES. LES length can also be measured. Shorter LES total length and intraabdominal length also make the LES effective. Relaxation (residual) pressure is measured by the integrated relaxation pressure (IRP)—the 4 seconds of lowest pressure in a 10-second measurement even if not consecutive. This will define a nonrelaxing LES.

Manometry can determine if there is a disjunction of the LES and diaphragm pressures (manometric hiatal hernia) (Fig. 83.4). In type I, diaphragmatic pressure and LES pressure components are coincident. In types II and III, there is a progressive separation of the components.

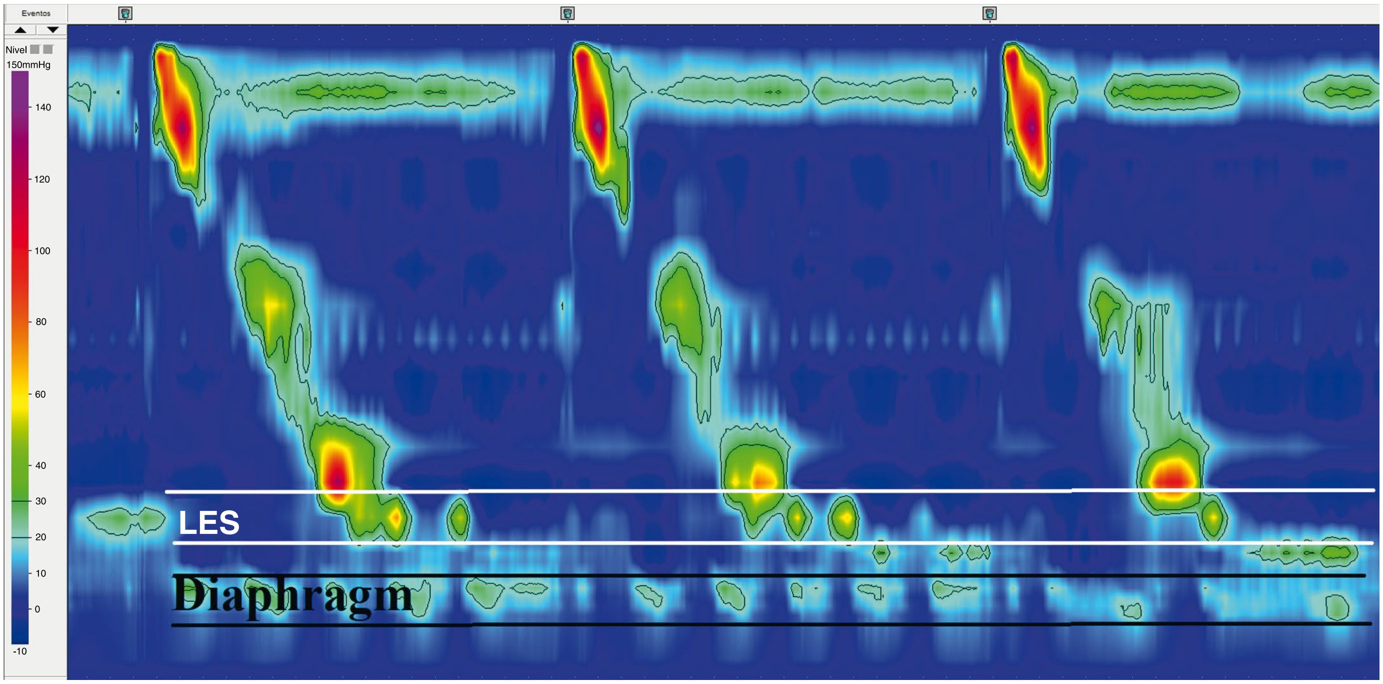

FIGURE 83.4 Esophagogastric junction type III by esophageal manometry. Note the separation of the lower esophageal sphincter *(LES)* pressure from the diaphragm.

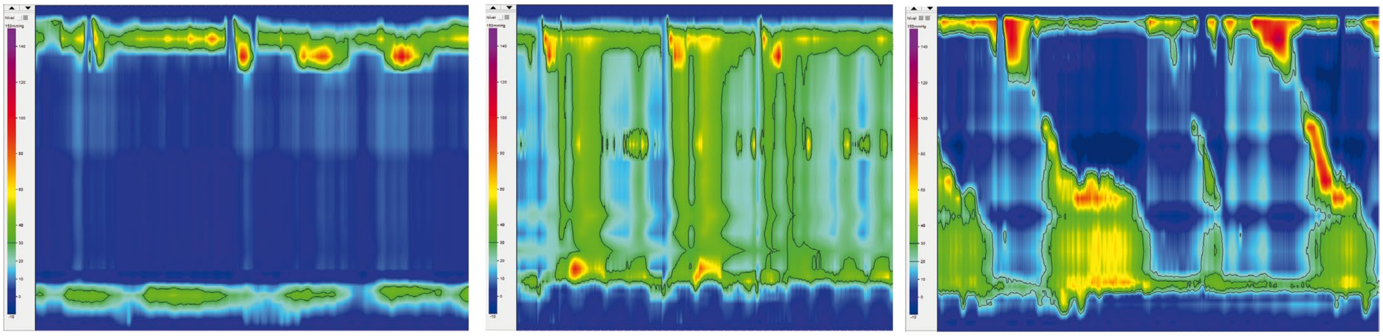

Type I Type II Type III

FIGURE 83.5 Achalasia types according to the Chicago classification.

Motility disorders associated with an abnormal LES relaxation are **achalasia** (in the absence of peristalsis) and **esophagogastric outflow obstruction** (in the presence of peristalsis). Achalasia is categorized into three groups according to esophageal pressurization[22,23] (Fig. 83.5):

Type I: incomplete LES relaxation, aperistalsis, and absence of esophageal pressurization
Type II: incomplete LES relaxation, aperistalsis, and panesophageal pressurization in at least 20% of swallows
Type III: incomplete LES relaxation, aperistalsis, and spastic contractions in at least 20% of swallows

Esophageal Body

When there is sufficient esophageal muscle force and coordination to push the bolus down to the stomach, esophageal body motility is normal.

An abnormal esophageal body characterizes the majority of motility disorders linked to GERD that can only be classified as primary disorders in the absence of GERD. The motility abnormality is regarded as secondary if GERD is present, and reflux should be the focus of treatment.

The distal latency (DL), which is measured as the period of time between the start of UES relaxation and the change from the esophageal body to the epiphrenic ampulla, is what determines coordination. Waves can be normal or premature. The disease of the lack of coordination is the distal esophageal spasm, defined as at least 20% of premature contractions with normal contractile vigor (Fig. 83.6). Symptoms of dysphagia or chest pain are necessary for a clinically significant diagnosis.[21]

The distal contractility integral (DCI), which is calculated as the product of the mean amplitude of contraction in the distal esophagus (mm Hg) times the contraction's duration(s) times the length of the distal esophageal segment (cm), determines force (contraction vigor). Depending on the DCI, waves can be failed, weak, normal, or hypercontractile.

The manometric disease defined by hypercontractile peristalsis is the **hypercontractile esophagus** (HE, previously nutcracker and jackhammer), defined by excessive contraction vigor in at

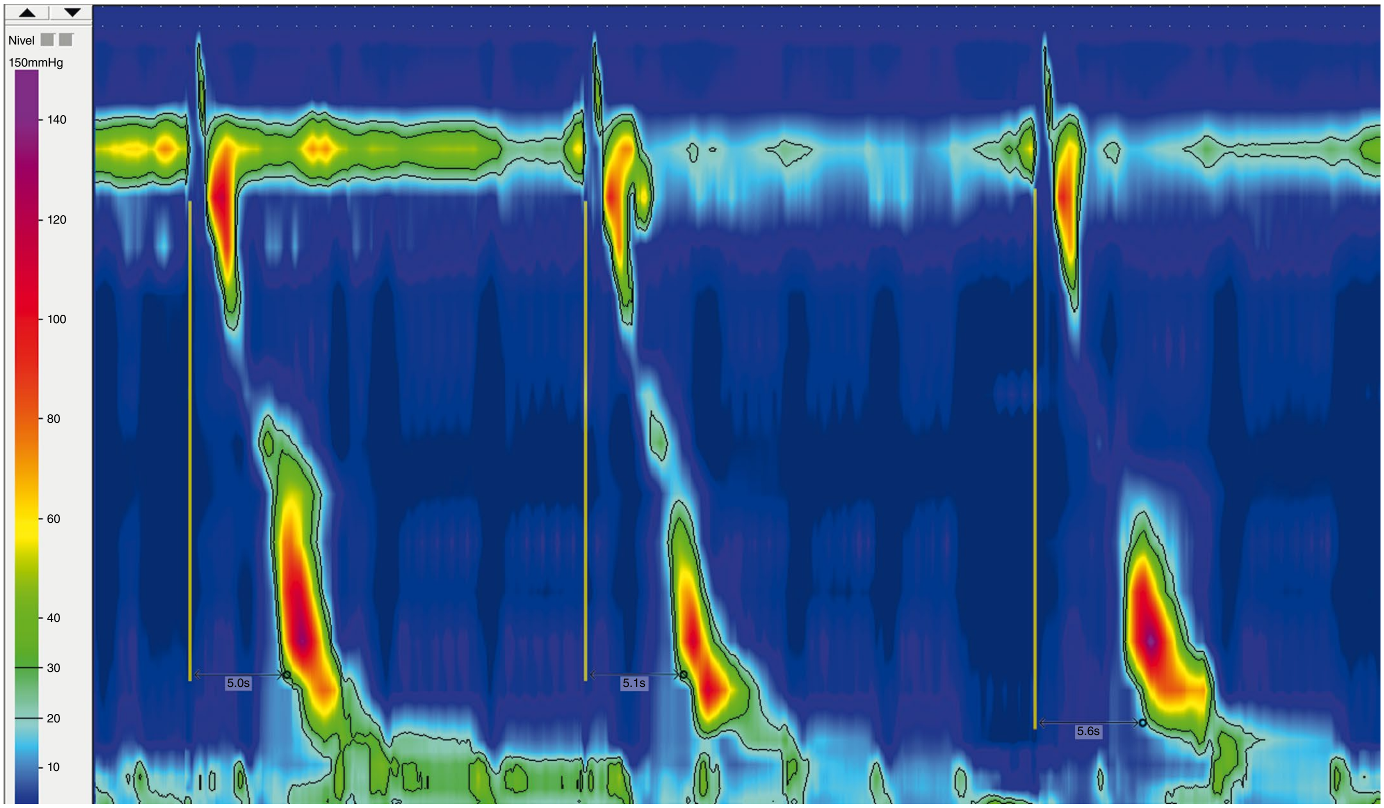

FIGURE 83.6 Distal esophageal spasm. Premature waves are shown.

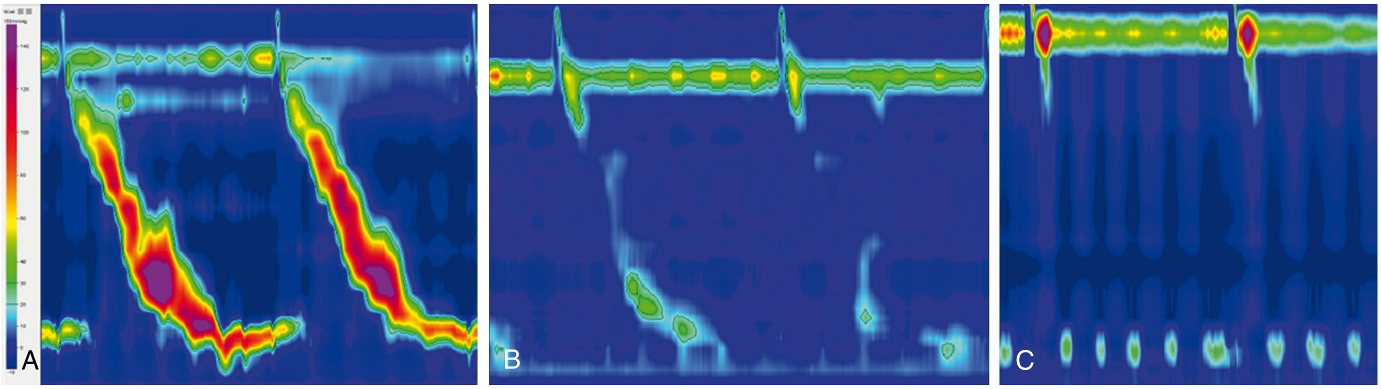

FIGURE 83.7 Diseases of the contraction vigor. Hypercontractile esophagus (A), ineffective esophageal motility (B), and absent contractility (C).

least 20 of the swallows. Similar to distal esophageal spams, the presence of symptoms is mandatory to distinguish between clinically relevant disease and clinically irrelevant manometric observations.[21]

The manometric disease defined by hypocontractile peristalsis is the **ineffective esophageal motility,** defined by presence of ≥70% ineffective swallows or ≥50% failed waves, and the **absent contractility,** defined by 100% failed peristalsis[21] (Fig. 83.7).

Upper Esophageal Sphincter

Because of technical limitations of manometry equipment, incomplete understanding of the anatomophysiology of the pharyngo-upper esophageal area,[24,25] and exclusion of the UES from the current guidelines, manometric evaluation of the UES has been neglected, with only a few studies evaluating patients with oropharyngeal dysphagia.[26]

Ambulatory pH Monitoring

Transnasal catheters, wireless esophageal mucosa capsules, and intraluminal impedance measurements can all be used for ambulatory pH monitoring.[27,28] Catheters allow multiple sensors to detect the height of reflux and are more unconformable but cheaper and more dependable. Although wireless capsules are more expensive, there is a significant loss of data due to radio interference, the presence of the capsule may cause chest pain, and there is a chance that it will come off too soon or too late. However, they are more tolerable and enable monitoring for periods longer than 24 hours. The test is usually performed immediately

TABLE 83.3 Indications for Ambulatory pH Monitoring

Diagnose GERD	- Symptoms suggestive of GERD - Organs possibly damaged by GERD
Associate GERD and symptoms	- Extraesophageal symptoms - Visceral hypersensitivity
Evaluate GERD severity	- DeMeester score - Pattern (supine, upright, combined)
Preoperative workup	- Exclude other motility disorders - Baseline comparison in cases of unfavorable outcome
Postoperative workup	- Unfavorable outcome - Continued damage to organs despite the operation

GERD, Gastroesophageal reflux disease.

after the esophageal manometry. Fasting is necessary, and antacid medications must be stopped. There is no good reason to perform the test under the influence of acid blockade.

Clinical guidelines usually indicate pH monitoring only when GERD is not proven by specific findings at the upper digestive endoscopy or after failure of empirical pharmacologic treatment. pH monitoring, however, also reveals information about the severity, pattern, and temporal relationship between reflux and symptoms (Table 83.3).

GERD can be present in a myriad of clinical scenarios. It may occur from the "classic" presentation, with esophageal symptoms, to a silent presentation only noticed by damage to target organs. Thus, objective evaluation is mandatory.[29,30]

A certain amount of reflux is considered physiologic and does not define GERD. Pathologic (abnormal) acid exposure can be simply defined by the percentage of time that the esophagus was acidic (pH <4) (acid exposure time [AET]) greater than 6%. Most surgeons, however, prefer the DeMeester score that accredits points to the following parameters: (1) total number of episodes of reflux; (2) % total time esophageal pH <4; (3) % upright time esophageal pH <4; (4) supine time esophageal pH <4; (5) number of reflux episodes ≥5 minutes; and (6) longest reflux episode (minutes). The DeMeester score is influenced by the pattern of reflux and esophageal clearance correlating clinically with GERD severity[31] (Fig. 83.8). GERD may occur predominantly in the orthostatic or supine position or in a combined pattern (bipositional).

The height that the reflux episodes reach can be estimated thanks to the inclusion of multiple sensors in the catheter. However, because there is no recognized reference value for proximal reflux, there is no standardization of technique, and few surgical studies addressed this; interpreting the height of reflux is very challenging.[32,33]

pH monitoring may calculate the temporal relationship between symptoms and reflux episodes. This association can be calculated using a variety of metrics. The most popular and simpler method uses the percentage of GERD-related symptoms compared with all other symptoms to define the symptom index (SI), which is positive when it is greater than 50%.[34]

PRIMARY ESOPHAGEAL MOTILITY DISORDERS

Esophageal motility disorders can be broadly subdivided into two categories:

1. PEMDs caused by esophageal diseases per se.
2. Secondary esophageal motility disorders caused by esophageal dysfunction that is part of more global disease, such as GERD or scleroderma.

The classification of PEMD is based on the findings of esophageal manometry. Traditionally, esophageal manometry was

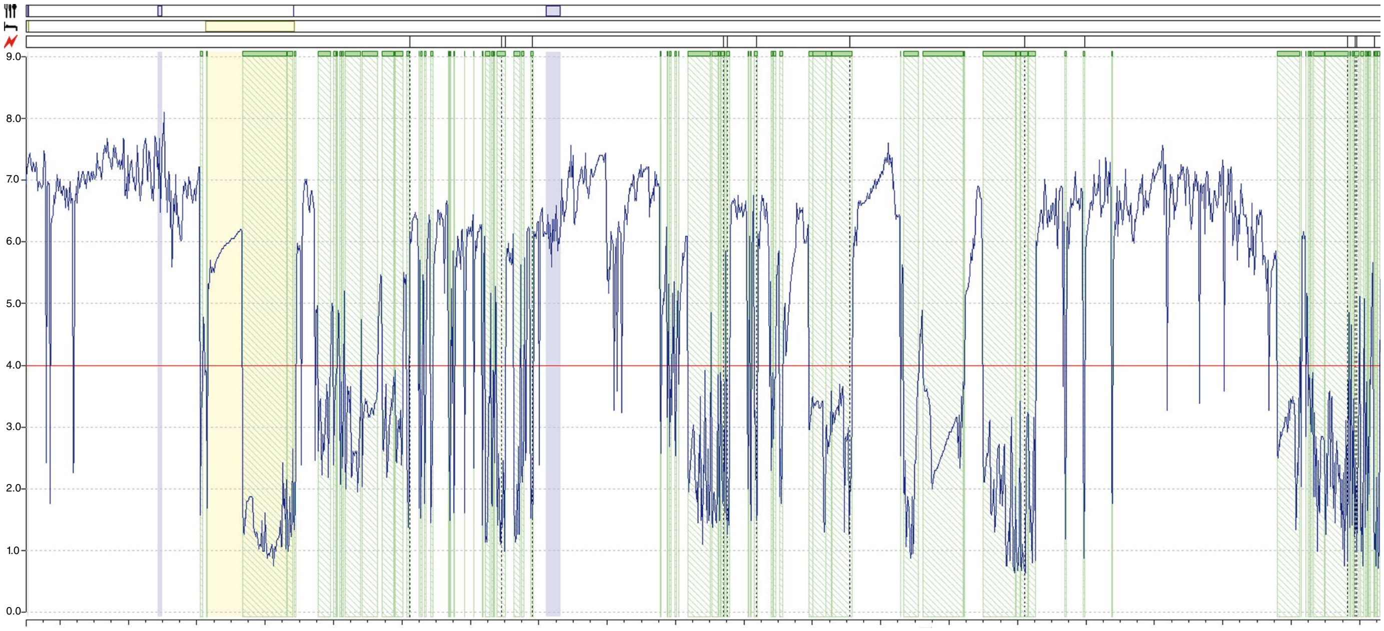

FIGURE 83.8 Example of pH monitoring traces. The *red horizontal line* represents pH = 4. All lines below the red line indicate an episode of reflux *(green rectangles).* DeMeester score will be calculated based on the six parameters, including these episodes of reflux. *Vertical dotted lines* represent the moments symptoms were reported. The temporal correlation between symptoms and reflux can be calculated. Meal times are excluded because acid can be originated in the food *(blue rectangles).*

performed with water-perfused catheters, often with a configuration with four distal circumferential sensors to measure the LES and four sensors spaced at intervals of 5 cm at 90-degree angles from each other (usually placed 3, 8, 13, and 18 cm above the upper border of the LES). Initially, the resting pressure, relaxation, total length, and abdominal length of the LES were assessed. Subsequently, 10 swallows of 5 mL of water were given at 30-second intervals for the evaluation of esophageal peristalsis (amplitude, duration, velocity, nontransmitted, or partially transmitted waves). Based on this test, four PEMDs were identified[35,36]: achalasia, diffuse esophageal spasm (DES), nutcracker esophagus, and hypertensive LES. Each disorder was characterized as follows:

- Achalasia: Partial or absent LES relaxation and absent esophageal peristalsis. Hypertensive LES (resting pressure >45 mm Hg) in about 50% of patients.[37]
- DES: Normal or elevated LES pressure. Simultaneous contractions after >20% but <100% of the wet swallows. Intermittent normal peristalsis. The contraction amplitude is usually >30 mm Hg.
- Nutcracker esophagus (hypercontracting esophagus): Normal or elevated LES pressure. Normal peristaltic progression with high-amplitude (>180 mm Hg) and long-duration (>6 seconds) waves in the distal esophagus.
- Hypertensive LES: Elevated LES resting pressure >45 mm Hg. The relaxation might be incomplete. Normal esophageal peristalsis.

Over the past 15 years, there have been significant advances in manometric device technology, manometric data display, and manometric data analysis.[38] In most centers, the water-perfused catheters have been substituted with solid-state catheters with 36 closely spaced pressure sensors, and data are displayed in the format of Clouse plots (color isobaric contours). Today high-resolution manometry (HRM) and the Chicago classification, now in version 4.0, are considered standard in clinical practice worldwide.[39]

Based on the Chicago classification, PEMDs are categorized as follows:

- Achalasia, with three subtypes: I, II, and III
- Esophagogastric junction outflow obstruction (EGJOO)
- DES
- HE
- Ineffective esophageal motility

Achalasia

Achalasia is a rare disease with an incidence of approximately 1 per 100,000 individuals. The disease occurs with equal frequency in males and females and in White and non-White individuals, and the mean age at diagnosis is about 50 years, with peaks around 30 and 60 years of age.[40] Interestingly, the prevalence of achalasia seems to be increasing, probably because of higher awareness of the disease and improved ability to establish the diagnosis.

The pathophysiology of achalasia involves the selective degeneration of inhibitory neurons of the esophageal myenteric plexus, which contain nitic oxide and vasoactive intestinal polypeptide, which are needed for peristalsis of the smooth muscle of the esophageal body and for relaxation of the LES.[41] The etiology of this degenerative process is still unknown. Some viruses such as varicella-zoster, human papilloma, and herpes have been implicated in initiating an inflammatory reaction. Interestingly, the excitatory neurons that contain acetylcholine are spared. Consequently, the LES does not relax properly, and it is often hypertensive.

In addition to the idiopathic form of achalasia, there are some secondary forms. One is Chagas disease, caused by the inoculation through a bug bite of a parasite, *Trypanosoma cruzi.* Organs other than the esophagus are also affected such as the heart, the brain, and the gastrointestinal tract. Another secondary form of achalasia known as *pseudoachalasia* is caused by malignancy, particularly cancer of the esophagus. Pseudoachalasia should be excluded in older patients (>60 years of age) who have been symptomatic for a short time and who have lost a considerable amount of weight.[42] Achalasia is also part of Allgrove syndrome (triple A) characterized by achalasia, alacrimia, and adrenal insufficiency.[43]

Clinical Presentation

Dysphagia, regurgitation, chest pain, heartburn, and aspiration are the most common symptoms experienced by patients with achalasia.[37] Because these symptoms can be caused by other diseases, there is often a delay between the onset of symptoms and the diagnosis of achalasia.

Dysphagia for solids and liquids is the most common symptom, present in approximately 95% of patients. Although some patients can make changes in their diet and maintain a stable weight, others experience progressive weight loss.

Regurgitation of undigested food occurs in about 70% of patients. It can cause aspiration with cough, hoarseness, and episodes of pneumonia.[44]

Heartburn is experienced by 40% to 50% of patients. It is not the result of esophageal reflux of gastric contents, but rather by stasis and fermentation of undigested food in the esophagus. Unfortunately, when heartburn is present, patients are often treated with acid reducing medications on the assumption that this symptom is caused by GERD. In the absence of a response to therapy, these patients are assumed to have “refractory GERD,” delaying the correct diagnosis, and even referred for antireflux surgery.[45] Chest pain is present in 40% to 50% of patients, and it is thought to be secondary to esophageal distention.

A clinical scoring system for achalasia (Eckardt score) is commonly used to assess the severity of the disease and the effect of treatment.[46] The Eckardt score attributes points (0–3) to four symptoms—dysphagia, regurgitation, weight loss, and chest pain—therefore ranging from 0 to 12. A score of 3 or less indicates successful treatment.

Diagnostic Evaluation

A thorough evaluation must be performed when a diagnosis of achalasia is suspected, as symptoms have low sensitivity and specificity. Esophagogastroduodenoscopy (EGD), barium swallow, and esophageal manometry should be performed routinely, reserving ambulatory pH monitoring to patients complaining of heartburn.

Esophagogastroduodenoscopy. This is the first test usually performed in patients complaining of dysphagia. In about 40% of patients, the test is normal, whereas in the remaining patients, retained food and saliva or esophagitis due to stasis of food or *Candida* infection are found (Fig. 83.9).

Barium swallow. This test provides information about the anatomy of the esophagus. Specific radiologic findings include distal esophageal narrowing, an air-fluid level, slow emptying of the contrast into the stomach, and tertiary contractions (Fig. 83.10). Information about the axis (straight vs. sigmoid) and the amount of dilatation is very important for planning treatment (Fig. 83.11). In addition, the test can show additional and

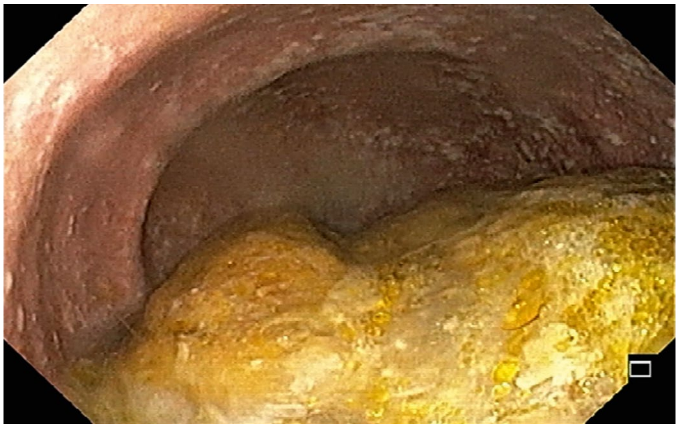

FIGURE 83.9 Endoscopy in a case of achalasia with food residues in the esophagus.

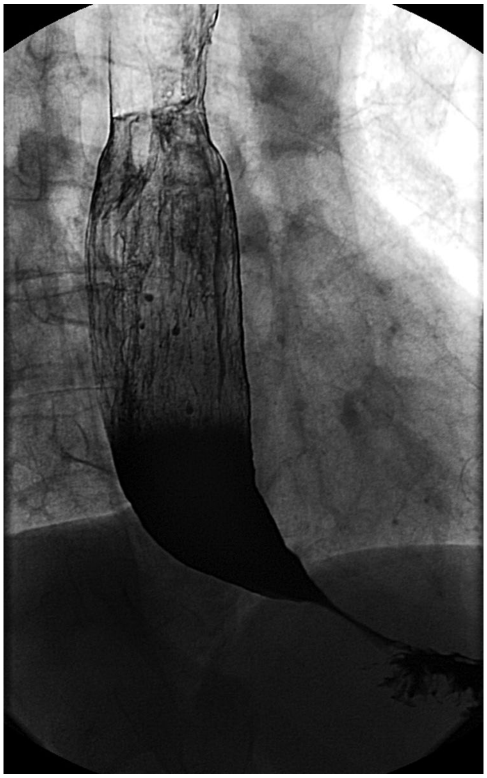

FIGURE 83.10 Barium swallow findings in a case of achalasia: distal esophageal narrowing, an air-fluid level, slow emptying of the contrast into the stomach, and tertiary contractions.

unexpected pathology such as an esophageal diverticulum. In early stages of the disease, the test can be normal in about 30% of patients.

Esophageal manometry. As mentioned before, high-resolution esophageal manometry is considered today the gold standard for the diagnosis of achalasia. In addition to establishing the diagnosis, this test defines the subtype of achalasia—type I, II, or III—with important implications for the choice and outcome of treatment.

Ambulatory pH monitoring. This test is recommended for patients who complain of heartburn to distinguish between GERD and achalasia. A recent study showed that 29% of patients whose final diagnosis was achalasia had been treated for an average of 29 months with proton pump inhibitors (PPIs) and eventually referred for antireflux surgery, as they were considered to have "refractory GERD."[45]

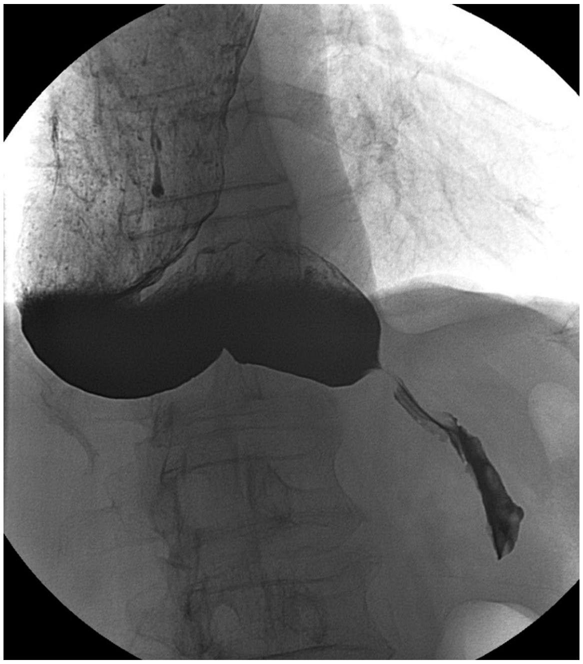

FIGURE 83.11 Dilated and sigmoid esophagus.

When analyzing the pH monitoring test, it is important to look not only at the reflux score or percentage pH <4 but also at the tracing. A positive score can in fact be caused by real reflux (intermittent drop of the pH below 3 with subsequent return to values above 5) or by false reflux secondary to stasis and fermentation of food in the esophageal lumen, with slow and progressive drift of the pH below 4 and a very slow return to higher values.[47]

Functional lumen imaging probe. The functional lumen imaging probe (FLIP) is a catheter-based system used to evaluate esophageal compliance in patients with achalasia. This test uses impedance planimetry to calculate the esophageal lumen dimensions and distensibility. In addition, it is used to corroborate findings from HRM and/or barium swallow and assess the effect of treatment.[48]

This is a relatively new technology, complementary to other tests, and its usefulness is not fully determined.

Treatment

Treatment is palliative, as it does not cure the disease. The goal of treatment is to decrease the functional obstruction caused by a nonrelaxing and often hypertensive LES, therefore improving emptying of food from the esophagus into the stomach. Various treatment modalities are available today: pharmacologic (calcium channel blockers, phosphodiesterase inhibitors), endoscopic (botulinum toxin injection, pneumatic dilatation [PD], peroral endoscopic myotomy [POEM]), and surgical (laparoscopic Heller myotomy [LHM] with partial fundoplication).

Pharmacologic treatment. Nifedipine is the most frequently used calcium channel blocker. In a placebo-controlled, double-blind crossover study, it was shown that even though nifedipine and verapamil decreased the contraction amplitude in the distal esophagus and the LES pressure, there was no significant improvement in the symptomatology.[49] More recently, the use of sildenafil, normally used for erectile dysfunction, has been investigated. This is an inhibitor of phosphodiesterase type 5 that inactivates the nitric oxide cyclic guanosine monophosphate (cGMP), thus increasing the intracellular levels of cGMP and therefore promoting the relaxation of smooth muscle cells. However, although this drug reduces the LES pressure, it has no effect on the LES relaxation. Overall, the symptom improvement is limited, the duration of action is short, and the efficacy decreases over time.[50]

Endoscopic treatment

Botulinum toxin injection. Botulinum toxin inhibits the release of acetylcholine at the level of the cholinergic synapses, thus decreasing LES pressure. It has no effect on LES relaxation. The standard protocol for the endoscopic botulinum toxin injection (EBTI) consists of the injection of 100 units of toxin in four quadrants, approximately 1 cm above the gastroesophageal junction (GEJ). A review and meta-analysis of the different treatment modalities for achalasia showed that EBTI determines relief of symptoms in approximately 80% of patients within a month after the procedure, but its effect decreases over time: 70% at 3 months, 53% at 6 months, and 40% at 12 months.[51] In addition to the decreased efficacy over time, some studies have shown that this treatment may cause an inflammatory process at the level of the injection with loss of the normal anatomic planes. Consequently, in patients undergoing LHM for recurrent dysphagia after EBTI, the operation may be challenging, with an increased incidence of mucosal perforation and worse outcome.[52,53] Based on these considerations, EBTI should be considered only in patients who are not fit for PD, LHM, or POEM.

Pneumatic dilatation. PD is an effective option for the treatment of esophageal achalasia. A graded approach should be used, starting with a 30-mm balloon, and reserving larger balloons (35 and 40 mm) for patients with persistent or recurrent symptoms. Many studies have shown that the results of PD are comparable to those of LHM, even though PD needs to be repeated in about one-fourth of patients. Predictors of poor response are persistence of symptoms after the first or second dilatation, age less than 40 years, male sex, large esophageal diameter, type I and III according to the Chicago classification, pulmonary symptoms, and postprocedure LES pressure >10 mm Hg.[54]

A European prospective and randomized trial comparing PD (starting with a 30-mm balloon and reserving 35- and 40-mm balloons for persistent or recurrent dysphagia) and LHM with a Dor fundoplication was published in 2011.[55] The primary outcome was therapeutic success (a drop in the Eckardt score to ≤3) at the yearly follow-up assessment. The secondary outcomes included the need for retreatment, pressure of the LES, esophageal emptying on a timed barium esophagogram, quality of life, and the rate of complications. After 2 years, the therapeutic success of PD (86%) or LHM (90%) was similar. At 5-year follow-up there was still no significant difference between the two treatments—84% LHM and 82% PD—but 25% of patients undergoing PD required addition dilatations.[56] No differences in secondary outcome parameter were observed.

Even though these results suggest that these treatment modalities are equivalent, some limitations of this trial need to be stressed. First, the protocol was revised during the study period, changing the initial PD technique using a 35-mm balloon to a 30-mm balloon after the observation of a 31% perforation rate with the 35-mm balloon. Second, expert gastroenterologists performed the PD, whereas the skills and experience of the surgeons involved in the study were questionable, as they were required to have performed just five myotomies to participate, and the mucosal perforation rate during LHM was 11%—very high in general and particularly in the absence of previous treatment. In addition, subgroup analysis showed that patients younger than 40 years had better results with LHM.

Finally, the applicability of the findings of this study to the practice in the United States is questionable. Because of the extensive use of LHM during the last 15 years, the expertise for PD has faded away considerably. Consequently, it seems that today the pendulum has swung toward either LHM or POEM as initial treatment for achalasia, reserving PD for the treatment of recurrent dysphagia after these two therapeutic modalities.

Surgical treatment. The past three decades have witnessed major changes in the surgical treatment of achalasia, moving from an open operation through either a laparotomy or thoracotomy to a thoracoscopic approach and eventually to a laparoscopic myotomy with a partial fundoplication (Dor or Toupet).

Laparoscopic myotomy with partial fundoplication (Fig. 83.12). The operation is usually performed with four or five trocars placed in the upper abdomen. After opening the gastrohepatic ligament, the right pillar of the crus is identified and dissected and the peritoneum and phreno-esophageal membrane above the esophagus are transected. The short gastric vessels are divided to avoid any tension when performing the fundoplication. The myotomy is usually about 8.5 cm in length, with 6 cm above the GEJ and 2.5 cm onto the gastric wall. After completion of the myotomy, the muscle edges are separated so that the esophageal mucosa is not covered by muscle fibers for about 140 degrees of circumference. Finally, a partial anterior fundoplication (Dor) or posterior (Toupet) is performed.[57] Each procedure has pros and cons: The Dor anterior fundoplication does not need dissection posterior to the esophagus, therefore avoiding the risk of damaging the posterior vagus nerve. The Toupet requires the posterior dissection, but it might help keep the muscular edges separated, therefore avoiding recurrent dysphagia. The minimally invasive technique has evolved over time as it became clear that a fundoplication was necessary to control postoperative reflux, that a 360-degree wrap determined too much resistance at the level of the GEJ causing dysphagia, and that a longer myotomy onto the gastric wall gave better results.[58,59]

The LHM has shown excellent results over the years. The Padua group reported a 90% success rate among 407 patients at a median follow-up of 2.5 years, with a 5-year actuarial probability of being asymptomatic of 87%.[60] The European multicenter study showed a success rate of 84% after 5 years.[56] The long-term results of a prospective and randomized trial in Sweden comparing PD and LHM showed that after the LHM, 92% of patients had excellent results after 5 years and 80% at 10-year follow-up.[61]

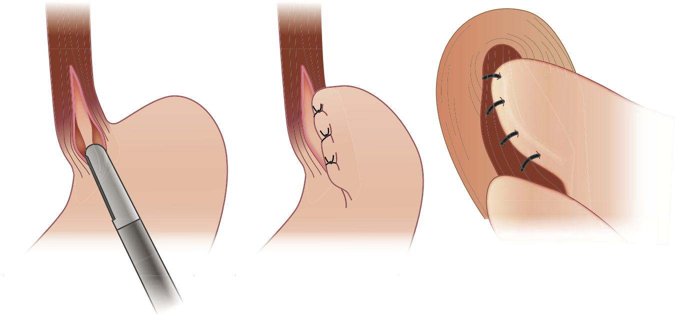

FIGURE 83.12 Laparoscopic Heller myotomy and partial fundoplication (Dor).

Recent years have shown an increasing use of robots to perform myotomy. The advantages of robotic surgery include improved visibility of the operative field with three-dimensional imaging, increased degrees of freedom of movements, and improved ergonomics. In addition, it might decrease the incidence of mucosal perforations, even though the long-term results are like those of an LHM.[62] Considering these findings, it seems that cost may remain a significant barrier to the widespread use of the robotic platform for the treatment of esophageal achalasia.

Peroral endoscopic myotomy. In 2010 Dr. Inoue published the results of a new endoscopic technique called *peroral endoscopic myotomy* (POEM) for the treatment of esophageal achalasia, showing clinical success in 100% of 17 patients with achalasia.[63] This initial report represents a milestone in the treatment of this disease, and today POEM is used in many centers across the world, either as primary treatment or for treating recurrent symptoms after PD or LHM.

The procedure is usually done under general anesthesia and consists of four steps: (1) submucosal injection and mucosal incision, usually 10 to 12 cm above the GEJ; (2) submucosal tunneling, extended past the GEJ for 2 to 3 cm onto the stomach; and (3) myotomy. The circular fibers are transected with preservation of the longitudinal fibers. The myotomy extends from 2 cm distal to the mucosal entry to 2 to 3 cm onto the gastric wall and (4) closure of the mucosal entry with clips or endoscopic sutures.

Many studies have shown that POEM is effective in relieving symptoms in more than 90% of patients, suggesting that it might be considered the primary treatment modality for patients with achalasia.[64–66] However, POEM has a clear “Achilles heel” due to a very high incidence of postprocedure GERD—around 50%—as the procedure is based on a myotomy alone without a fundoplication.[67,68] This finding reproduces the results of the prospective and randomized trial comparing a laparoscopic myotomy alone with a laparoscopic myotomy and Dor fundoplication.[69] Postoperative GERD was present in 48% of patients after myotomy alone but in 9% alone when a Dor fundoplication was added. The relief of dysphagia was similar in the two groups. A meta-analysis comparing the efficacy of POEM and LHM and the incidence of postprocedure reflux in patients with achalasia showed that the control of symptoms was excellent with either procedure (at 2-year follow-up, 92.7% after POEM and 90% after LHM). However, pH monitoring showed that the incidence of pathologic reflux was more than fourfold higher after POEM as compared with LHM (47.5% vs. 11.1%).[70] These findings have been recently confirmed in a multicenter, randomized controlled trial (RCT) comparing the endoscopic and the surgical myotomy in patients with esophageal achalasia.[71] A total of 221 patients were randomized to either POEM (112 patients) or LHM (109 patients). At 2-year follow-up, clinical success was observed in 83% of patients in the POEM group and in 81.7% in the LHM group. The incidence of pathologic reflux was 57% after POEM and 20% after LHM.

This high incidence of GERD must be considered when treatment is chosen, particularly in young patients, as a lifelong exposure to reflux can cause esophagitis, Barrett esophagus, and even adenocarcinoma.

The achalasia subtype, shown by HRM, must be taken into consideration when planning treatment. Both LHM and POEM can be chosen as primary treatment for type I and II achalasia, but POEM is superior to LHM for type III, probably because it allows a longer myotomy onto the esophageal wall.[72,73]

Evaluation and Treatment of Recurrent Symptoms After Prior Intervention

Particularly when treating young patients, it is quite common that some degree of dysphagia recurs, necessitating additional treatment. Scarring of the distal aspect of the myotomy is probably the most common cause. This can occur despite performing a long myotomy onto the gastric wall and separating the edges of the myotomy. Gastroesophageal reflux can also play a role, with the development of a peptic stricture. In addition, it is always important to confirm the diagnosis of achalasia and to rule out technical problems at the time of the first intervention.[74]

The first step should be to review the history and the tests performed to establish the diagnosis (did the patient really have achalasia?). It is important to review the operative report of the original procedure, as it can help understand the cause of failure: For instance, in case the initial treatment was an LHM, was the surgeon able to identify the anatomic planes? How long did the myotomy extend onto the gastric wall? Was a 360-degree fundoplication performed rather than a partial one?

A full workup is necessary to try to identify the cause of the recurrent symptoms. A barium swallow is probably the most useful test assessing the anatomy and the emptying of the barium from the esophagus into the stomach. An upper endoscopy should always be performed to rule out a stricture caused by reflux, *Candida* esophagitis, or cancer. If pseudoachalasia is suspected, an endoscopic ultrasound and a CT scan of chest and abdomen should be obtained. Esophageal manometry is essential to confirm the diagnosis and to measure pressure and length of the LES. Finally, a 24-hour pH monitoring should be obtained to see if pathologic reflux is present.

If the PD was used as a first step and dysphagia is still present after repeated dilatation, either POEM or LHM can be used.

If the initial treatment was POEM, PD, a repeat POEM, or LHM should be used depending on the expertise of the center. However, if POEM was performed on the anterior wall of the esophagus and stomach, an LHM might be very difficult.

In case of recurrent dysphagia after LHM, PD can alleviate the symptoms in most patients.[26] POEM avoids a challenging redo operation because of the presence of adhesions and scar tissue and can be done safely on the posterior wall of the esophagus.[75–77] An esophagectomy should be considered a last resort, only after the failure of all the other treatment modalities.

End-Stage Achalasia

An esophagectomy was traditionally recommended as primary treatment of patients with a dilated and sigmoid esophagus, so-called “end-stage achalasia,” on the assumption that a myotomy could not improve the swallowing status.[78] However, some studies have shown that when the myotomy is performed by experienced surgeons, symptoms can be alleviated and an esophagectomy avoided in most patients.[79,80] In these patients, the operation is more challenging for the following reasons: (1) extensive dissection must be done in the posterior mediastinum in order to straighten the esophageal axis and bring more esophagus below the diaphragm; (2) the esophageal wall is usually very thick; (3) because of the extensive dissection, the esophageal hiatus can be enlarged, and stitches might be necessary to approximate the crura, usually posteriorly, avoiding angulation of the esophagus; and (4) if possible, a partial fundoplication should be added to the myotomy; however, if the esophagus is very dilated (8–10 cm), a fundoplication is not feasible.

Esophagectomy is more challenging than in patients with cancer, as the dilated esophagus occupies most of the posterior mediastinum and the feeding vessels are usually quite enlarged.

In 2001, a report of 93 patients who underwent an esophagectomy showed a very high incidence of complications: anastomotic leak (10%), recurrent laryngeal nerve injury (5%), bleeding requiring thoracotomy (2%), chylothorax (2%), and two patients died. In addition, 50% of patients developed an anastomotic stricture requiring dilatation.[78] A recent meta-analysis of eight studies comprising 1307 patients who had esophagectomy for achalasia (transthoracic 78.7%; transhiatal 21.3%) showed pneumonia in 10% of patients, anastomotic leak in 7%, and mortality in 2% of patients.[81] Overall, based on these results, a myotomy should be considered the first line of treatment, reserving an esophagectomy for patients who are still symptomatic after other interventions.

Considering the rarity and the complexity of this disease, the best results are obtained when patients are evaluated by a multidisciplinary group of experts and treatment is tailored to the individual patient.

Nonachalasia Esophageal Motility Disorders

Esophagogastric Junction Outflow Obstruction

A manometric diagnosis of EGJOO is defined as an elevated median IRP and ≥20% swallows with elevated intrabolus pressure in the supine position, with evidence of peristalsis (therefore not meeting the criteria for achalasia).[5] EGJOO can be idiopathic with normal anatomy or secondary to a hiatal hernia, a peptic stricture, or eosinophilic esophagitis. For this reason, a conclusive diagnosis requires relevant symptoms (dysphagia, regurgitation, chest pain) and additional tests such as a barium swallow, EGD, and/or FLIP.

When the EGJOO is secondary to other conditions such as a hiatal hernia, addressing them will alleviate the symptoms.[82] When EGJ is a primary problem, the same therapeutic approach for achalasia can be used to alleviate the distal esophageal obstruction. There are limited data about the effect of therapy in the idiopathic form of EGJOO, but it seems that both POEM and an LHM can be successful in alleviating symptoms in a high percentage of patients.[83,84]

Distal Esophageal Spasm

DES describes a specific abnormal esophageal motor pattern characterized by spastic or premature contractions in at least 20% of swallows in the distal esophagus and DL <4.5 seconds.[39] However, to define DES as PEMD, it is important to perform a pH monitoring study to rule out GERD. It has been shown that up to 40% of patients with GERD diagnosed by pH monitoring have a picture compatible with DES on HRM.[85] Clinically relevant symptoms for DES include dysphagia, noncardiac chest pain, regurgitation, and heartburn. Unlike achalasia, dysphagia is not progressive and weight loss is rare. Chest pain may mimic myocardial infarction, and it is usually described as a crushing or squeezing pain that can radiate to the jaw, arms, or back. In addition to the esophageal function tests, a barium swallow, an EGD, FLIP, and a cardiac evaluation are usually performed.

Once a solid diagnosis is established in a symptomatic patient, different therapeutic options are available. Overall, pharmacologic therapy has a limited role in the treatment because of limited efficacy and adverse side effects. Recently, peppermint oil has been used with some success in patients with DES, improving dysphagia and chest pain, although further studies are needed.[86] In patients with persistent symptoms who do not respond to medical therapy, an LHM or POEM can achieve good results. A retrospective study involving 11 centers that included 17 patients with DES and 18 with jackhammer esophagus found that POEM improved chest pain in 87% with clinical success (based on Eckardt score) of 84.9% with median follow-up of 272 days.[87] Surgical myotomy has also been studied in a small prospective study of 20 patients with extended myotomy for DES (the myotomy extended upward for 12–16 cm above the cardia and downward for 2 cm below the EGJ) and found that both dysphagia and chest pain improved in 100% and 90%, respectively, over 50-month follow-up.[88]

Because of the lack of well-controlled, long-term randomized controlled trials (RCTs), POEM and LHM for treatment of spastic esophageal body disorders should be reserved for highly selected patients because long-term prognosis even without treatment seems to be good for these disorders.

Hypercontractile Esophagus

A clinically relevant diagnosis of HE (jackhammer esophagus) requires both the presence of dysphagia and noncardiac chest pain and HRM showing 20% or more hypercontractile supine swallows with DCI >8000 and normal DL.[39] Hypercontractility can be limited to the esophageal body or can include the LES. In addition to HRM, an EGD should be performed to rule out the presence of eosinophilic esophagitis, which can determine the same symptoms and findings on HRM, requiring treatment with acid-reducing medications and steroids.[89]

This is a rare disorder, with a low prevalence around 2%, and a standard treatment has not been established thus far.[90] A multicenter study from Japan provided important information about the need and the outcome of treatment.[91] It reported that 77% of patients (13 patients) did well without treatment; POEM was successful in 76% of 21 patients, and laparoscopic myotomy in 2 of 2 patients (100%). Patients who required invasive treatment usually had a higher DCI and more severe disability. A systematic review and meta-analysis have shown that POEM was very successful in patients with spastic esophageal disorders, determining good results in 92% of patients with type III achalasia, 88% for DES, and 72% for HE.[92]

Overall, nonachalasia esophageal disorders are quite rare, and the best results are obtained in specialized centers where a complete workup can be performed and treatment tailored to the individual patient based on the symptoms, diagnostic findings, and expertise of the physicians.

ESOPHAGEAL DIVERTICULA

Esophageal diverticula are classified based on their location within the esophagus:

- Pharyngoesophageal (Zenker's) diverticulum
- Midthoracic diverticulum
- Epiphrenic diverticulum

Pharyngoesophageal (Zenker's) Diverticulum

This is the most common of the esophageal diverticula. Most patients are over age 60, and it is more common in males than in females. This diverticulum originates from the posterior wall of the esophagus, in a triangular area (Killian triangle) limited inferiorly by the cricopharyngeal muscle and laterally by the oblique fibers of the inferior constrictor of the pharynx (Fig. 83.13). When the diverticulum gets bigger, it tends to deviate from the

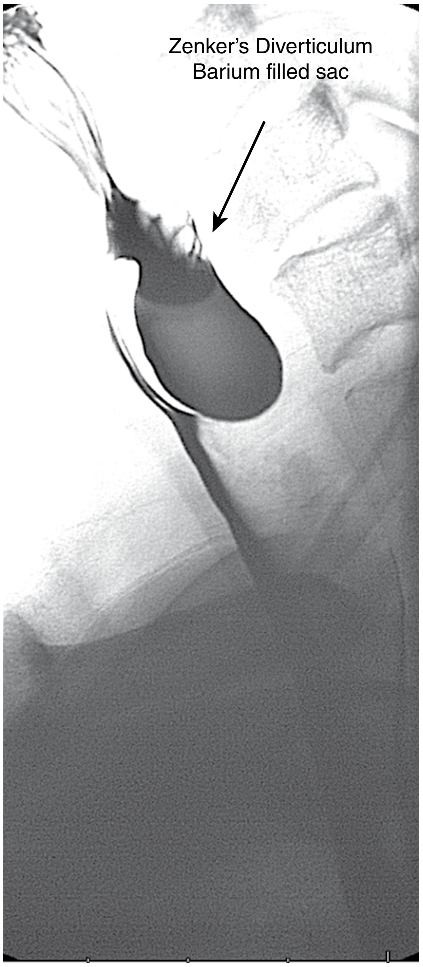

FIGURE 83.13 Zenker's diverticulum.

midline, mostly toward the left. A Zenker diverticulum is usually secondary to a lack of coordination between the pharyngeal contraction and the opening of the UES; therefore, it is a *pulsion* diverticulum secondary to increased intraluminal pressure. Only mucosa and submucosa herniate through the Killian triangle (false diverticulum).[93] Another area of potential weakness where a diverticulum can form is the so-called "Killian-Jamieson area" located just below the cricopharyngeal muscle.

Dysphagia is the most common symptom, present in about 80% to 90% of patients. Regurgitation of undigested food from the diverticular pouch occurs often and can lead to aspiration and pneumonia. Patients can also experience halitosis and hear gurgling sounds in the neck. About 30% have associated GERD.

A barium swallow shows the position (at the level of C5–C6) and size of the diverticulum or a prominent cricopharyngeal bar without an associated diverticulum. Endoscopy to rule out other pathology must be performed with great caution to avoid perforation. Esophageal manometry can show lack of coordination between the pharynx and UES and a hypertensive UES. It also locates the LES for ambulatory pH monitoring in patients suspected of having GERD—information especially useful to guide therapy.

Treatment consists of eliminating the functional obstruction of the UES with a myotomy of the cricopharyngeus muscle and the upper 3 cm of the posterior esophageal wall.[94] Traditionally, this approach was performed using a cervical incision, and the myotomy was associated with either excision or suspension of the diverticulum. A diverticulum less than 2 cm rarely requires treatment. Today transoral alternatives to ablate the septum between the esophagus and the esophageal diverticulum are available with particularly good results.

Open Transcervical Approach

A left-sided incision in the neck is made, following the medial border of the sternocleidomastoid muscle. Dissection is continued until the prevertebral fascia is reached. Usually there is no need to divide muscles. Once the esophagus and the diverticulum are identified, the cricopharyngeus muscle is divided completely and the myotomy is extended onto the esophageal muscle wall, exposing the esophageal mucosa for 3 cm below the diverticulum. There is no need to dissect the esophagus circumferentially because it increases the risk of damage to the left recurrent laryngeal nerve.

Small diverticula (<2 cm) should not be resected. Large diverticula can be resected or fixed upward to the prevertebral fascia. Resection is usually accomplished using a stapling device. Before stapling the neck of the diverticulum, it is important to place a bougie inside the esophagus to avoid pulling too much mucosa with consequent narrowing of the esophageal lumen. Infection, leak and mediastinitis, esophageal stenosis, and recurrent laryngeal nerve damage are the most common complications and occur in about 2% to 3% of cases. The recurrence rate of the diverticulum is between 5% and 10%.

If the preoperative evaluation has shown the presence of pathologic gastroesophageal reflux, either medical or surgical therapy should be prescribed to avoid the risk of aspiration, as it is increased after the resection of the UES.

Endoscopic Approach

Two different approaches are available: rigid endoscopy or flexible endoscopy. To date, no controlled trials have been performed to compare the two techniques, and, consequently, there are no guidelines for the management of this rare esophageal disorder.

Rigid endoscopic technique. The procedure is performed under general anesthesia with the patient in supine position with the neck extended. A diverticuloscope is introduced through the mouth, placing one blade inside the esophagus and one inside the diverticular pouch. After suctioning any undigested food, saliva, and pills, two stay sutures are placed on each side of the septum to obtain traction and facilitate the insertion of a modified linear stapler with the jaws across the septum. Firing the stapler creates a common cavity between the esophagus and the diverticular pouch.[95,96]

Flexible endoscopic technique. The rigid endoscopic technique has some limitations such as the need for general anesthesia and the need for hyperextension of the neck. In addition, small diverticula (2–3 cm) do not allow proper positioning of the stapler. The flexible endoscopic technique is performed with the patient on a left lateral decubitus, and the transection of the septum is done under direct vision. Division of the septum can be performed with different devices such as a needle knife, a hook knife, or argon plasma coagulation. After septotomy is completed, one or more endoclips are placed to close the incision and avoid leaks or bleeding.[97,98] Both the rigid and flexible endoscopic techniques have a success rate of 90%.

Z–Peroral endoscopic myotomy. POEM has been used for more than 10 years for the treatment of esophageal achalasia, with excellent results. This technique has been recently applied successfully for the treatment of Zenker's diverticulum.[99] The procedure starts with a submucosal injection and mucosotomy about 3 cm proximal to the septum, and then a submucosal tunnel is created along both sides of the septum, ending in the normal esophagus 2 cm distally to the end of the septum. The fibers of the cricopharyngeus muscle are transected under direct vision, and the mucosotomy is then closed with clips. Good results are obtained in 90% of patients, with a complication rate around 6%, mostly due to perforation or bleeding. As this is a new procedure, long-term results are not available.

Midesophageal Diverticulum

A midesophageal diverticulum is in the midportion of the thoracic esophagus. This is considered a *traction* diverticulum, secondary to an inflammatory process in the mediastinum, most frequently from histoplasmosis or tuberculosis. They are most seen on the right because of the close association of the esophagus with the subcarinal lymph nodes in this area. As the entire esophageal wall forms the diverticulum, this is considered a true diverticulum.

These diverticula are generally small and asymptomatic and do not need treatment. Larger diverticula (>4 cm) can become symptomatic and cause dysphagia. The workup consists of a barium swallow to identify size and location and an endoscopy to rule out cancer. In addition, an esophageal manometry should be performed because it has been suggested that a motility disorder is often present.[100]

Treatment of the symptomatic diverticula consists of a diverticulectomy through either a thoracotomy or a thoracoscopic approach.[101] A myotomy should be added if a motility disorder is present.

Epiphrenic Diverticulum

Epiphrenic diverticulum is a pulsion diverticulum usually located in the distal 10 cm of the esophagus. It is caused by the herniation of mucosa and submucosa through the muscle layers of the esophageal wall. Almost 60 years ago Belsey suggested that this diverticulum is not a primary disorder, but it is rather secondary to an underlying esophageal motility disorder so that treatment must address not only the diverticulum but also the motility disorder by a myotomy.[102] This brilliant intuition was confirmed in the following decades and today constitutes the basis for the modern treatment of epiphrenic diverticula. Esophageal achalasia and DES are identified by conventional manometry in about 70% of cases; when ambulatory manometry is used, a motility abnormality is present in every patient.[103,104]

The symptoms experienced by the patients are secondary to the underlying motility disorder. Dysphagia and regurgitation are the most common, followed by chest pain and weight loss. Aspiration can cause nocturnal cough, laryngitis, and pneumonia. Some patients experience heartburn, which is not caused by real reflux, but rather by stasis and fermentation of undigested food in the esophageal lumen. Bleeding, perforation, and malignant transformation are rare.

The barium swallow is a key test in patients with epiphrenic diverticulum, as it defines the size of the diverticulum and its neck, the location (about two-thirds are located on the right side), and the distance of the diverticulum from the GEJ (Fig. 83.14). About 15% of patients have more than one diverticulum.[104]

Endoscopy should be performed in all patients with dysphagia to rule out cancer; in addition, it can help with the placement of the manometry catheter. Manometry identifies the motility disorder, but it might be considered of academic interest, as it does not influence management.

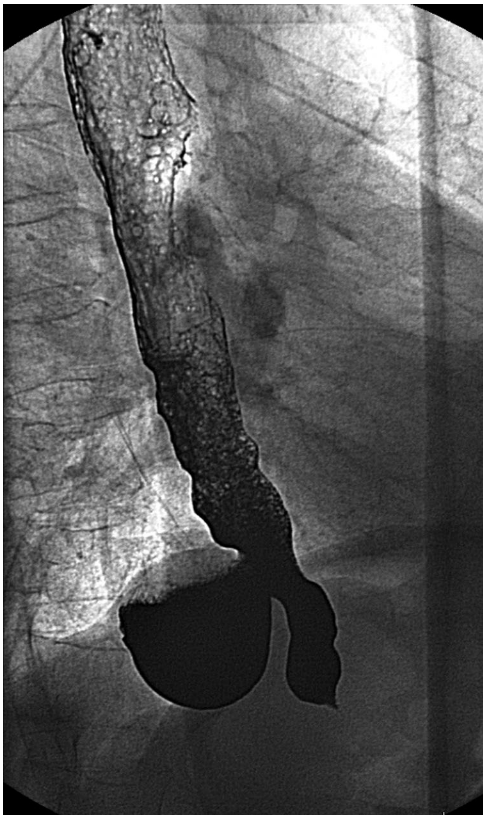

FIGURE 83.14 Epiphrenic diverticulum.

Treatment is recommended for symptomatic patients only for two reasons: (1) fewer than 10% of asymptomatic patients eventually develop symptoms,[105] and (2) even in expert hands, the operation carries significant morbidity.[106]

The transthoracic approach through a left thoracotomy has been traditionally used to treat epiphrenic diverticulum. This approach provides excellent exposure for the dissection, for the resection of the diverticulum with oversewing of the staple line, for a myotomy, and for a partial fundoplication, either a Dor or a Belsey.[104,106] However, even in the hands of expert surgeons, this approach is associated with significant morbidity. For instance, Varghese et al. reported on 35 patients operated on between 1976 and 2005 and showed that although relief of symptoms occurred in 74% of patients, 21% required periodic dilatations for treating dysphagia, there were two leaks (6%), and one patient died (3%).[106]

In 1988, Rosati described the laparoscopic approach to epiphrenic diverticulum, consisting of diverticulectomy, myotomy, and partial fundoplication.[107] The same group later described the long-term results of this approach in 20 patients.[108] At a median follow-up of 52 months, the results were excellent in 16 patients (80%).

These are the steps of a laparoscopic operation:

1. Dissection of the diverticulum and the diverticular neck.
   It is particularly important to completely dissect the neck circumferentially and identify the muscle layers before firing the stapler.
2. Transection of the diverticular neck.
   A 50-Fr to 56-Fr bougie must be placed inside the esophagus to avoid narrowing of the lumen when the stapler is applied.

Using a reticulating stapler allows optimal positioning across the neck of the diverticulum. The staple line is covered with interrupted stitches using nonabsorbable sutures.

3. A myotomy is then performed on the contralateral side of the esophagus.

   The myotomy extends from the level of the diverticular neck all the way down for 2 to 2.5 cm onto the gastric wall.
4. Closure of the crura, as often the hiatus is quite enlarged after an extensive dissection.
5. A partial fundoplication, either a Dor or a Toupet, is then performed.[109]

Sometimes the laparoscopic approach can be challenging if the diverticulum is very large (8–10 cm), if there is severe inflammation, or if it is not possible to safely dissect the neck circumferentially. In these cases, based on the consideration that the symptoms are mostly caused by the underlying motility disorder, it is reasonable to perform only a myotomy and partial fundoplication as described in patients with achalasia, without a diverticulectomy. The results of this approach are good in most cases, and very few patients eventually need a second operation to resect the diverticulum.[110,111]

Peroral endoscopic myotomy (D-POEM) has been used recently for the treatment of epiphrenic diverticulum with a remarkably high success rate.[112,113] Similar to laparoscopic myotomy alone, D-POEM can relieve the symptoms of dysphagia and regurgitation without the need for resection of the diverticulum. Compared with a surgical myotomy and fundoplication, D-POEM has the advantage of allowing a longer myotomy in patients with type III achalasia and DES. The major drawback of this technique is the absence of an antireflux procedure, with rates of pathologic reflux between 40% and 50%.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is the most common benign gastroesophageal disorder. It carries significant implications for patients' quality of life and is inextricably linked with other medical conditions, including esophageal adenocarcinoma, pulmonary disease, and obesity. Though most patients with GERD benefit from medical therapy, surgery still has an essential role in patients with medically refractory disease. Given the complex interplay of factors underlying GERD, the surgical approach should be tailored to patients' anatomy and pathophysiology.

Pathophysiology

As described previously in this chapter, GERD may arise if GEJ pressure is lower than the transdiaphragmatic pressure gradient. GEJ pressure, however, is not determined by any one structure, but instead is a complex of anatomic features—including the intrinsic muscle of the LES, the gastric sling fibers, the diaphragmatic crura, and the angle of His.[114] Alterations to any of these anatomic structures can predispose to reflux.

Evaluation

Evaluation of patients with suspected GERD begins with a detailed history. Patients often complain of "reflux"; however, GERD is a diagnosis, not a symptom. It is important to elicit specific symptoms, such as heartburn, regurgitation, waterbrash, dysphagia, and chest or abdominal pain. Heartburn and regurgitation are the most common symptoms, with regurgitation indicating more severe disease. Waterbrash is an increase in saliva production in response to acid reflux. Dysphagia may signal an underlying motility disorder or obstructing lesion. Bloating may signal an issue with gastric emptying. Patients may also have atypical or extraesophageal symptoms such as cough, shortness of breath, globus sensation, and throat clearing. Patients reporting chest or upper abdominal pain in the setting of cardiovascular risk factors must always have a cardiac cause excluded. It is essential to inquire about comorbid conditions, including pulmonary disease and obesity, as well as whether medical therapy has been tried and been effective. Relief of symptoms with PPIs predicts a good response from fundoplication. PPI therapy may successfully address heartburn in many patients but may not address regurgitation or dysphagia or eradicate the extraesophageal symptoms. Lack of response to PPI may also indicate an alternative disease process. In addition to the GERD workup described next, patients with extraesophageal symptoms require additional testing to rule out primary disorders of the lungs, airway, or oropharynx. Physical examination is often unrevealing in cases of GERD; however, in some cases, dental changes, throat clearing, or cough may be apparent. Central obesity is a major risk factor for GERD and should be assessed by, at a minimum, calculating the patient's BMI.

Diagnostic Workup

Often in the primary care setting, PPI therapy is initiated empirically for suspected GERD. However, if patients' symptoms are severe enough to warrant surgical evaluation, they generally ought to undergo four diagnostic tests before intervention, according to expert consensus guidelines.[115] This workup serves several purposes: (1) to establish that the patient's symptoms are caused by GERD rather than an alternate diagnosis, (2) to identify important conditions that must be addressed during or before any intervention for GERD, and (3) to rule out motility disorders that may mimic GERD or affect the success of antireflux surgery.[116]

Barium Swallow

A barium swallow (aka upper GI series) is commonly performed in the initial assessment of GERD. It can evaluate hiatal hernias in detail as well as obstructing lesions such as webs or strictures. It can also identify gastroesophageal reflux events, though it is not sufficient to establish the diagnosis of GERD. Barium swallow can also provide some information regarding esophageal motility, though it is not the gold standard test for this. If a paraesophageal hernia is found on barium swallow and it is causing classic symptoms, ambulatory pH monitoring and esophageal manometry might not be necessary before proceeding to definitive surgical treatment.

Upper Endoscopy

Upper endoscopy is essential before performing antireflux surgery. This may establish the diagnosis of Barrett esophagus or reflux esophagitis and rule out malignancy in the esophagus or stomach before proceeding to surgery. LA class C and D esophagitis, peptic strictures, and Barrett esophagus are pathognomonic for GERD. Assessing the GEJ on retroflexion may also provide information on the presence of a hiatal hernia and the integrity of the LES complex.

Ambulatory pH Monitoring

Ambulatory pH monitoring is the gold standard test for the diagnosis of GERD. Earlier in the chapter we discussed how it is performed and how to interpret the findings. pH monitoring is typically performed off acid suppression, but this topic is controversial, and the most recent consensus guidelines do suggest a role for pH monitoring while on acid suppression.[117] pH monitoring performed off PPI is typically used to make the diagnosis of GERD. Acid exposure calculations will be artificially decreased if the patient is on a PPI, and a diagnosis may be missed if testing is performed on a PPI. However, for patients who already have an established diagnosis of GERD, pH monitoring on a PPI may be useful to assess if acid suppression is adequate and/or if symptoms might be related to nonacid issues, which could be addressed nonoperatively.

Esophageal Manometry

Esophageal manometry is used to identify achalasia and other disorders of esophageal motility before antireflux surgery, as patients with poor motility may not tolerate a full fundoplication. However, prolonged acid exposure can also cause esophageal dysmotility that may improve with surgery. Distinguishing dysmotility that may preclude antireflux surgery from dysmotility that may benefit from antireflux surgery can be challenging. The multiple rapid swallows maneuver assesses esophageal “reserve”; patients with dysmotility but a normal multiple rapid swallows response tend to see improvement of dysmotility after antireflux surgery without worsening dysphagia. Esophageal manometry is not required before surgery in patients with paraesophageal hernias because they can make manometry testing unreliable.

Treatment

Medical Management

By the time patients present for surgical evaluation for GERD, they have often initiated medical therapy, typically in the form of a PPI. Surgeons should inquire about both lifestyle and medical treatments attempted during treatment for GERD because antireflux surgery is typically only indicated for patients refractory to maximal medical management. Lifestyle approaches include weight loss, avoiding dietary triggers, elevation of the head of the bed, tobacco, alcohol cessation, and avoiding late night meals.

Over-the-counter antacids such as Tums may offer temporary relief but are not effective in healing esophagitis. H_2 blockers such as famotidine may be useful for breakthrough symptoms and are stronger than antacids but can be limited by tachyphylaxis or tolerance with repeated dosing and low potency relative to PPIs.

PPIs are currently the most potent antisecretory therapy available. They have the highest rates of symptom control and healing of esophagitis. The various PPIs appear to be equally effective at equivalent doses, though some find certain formulations to be better than others. Guidelines by the American Gastroenterological Association recommend that patients with suspected uncomplicated GERD undergo a 4- to 8-week trial of a PPI, beginning at once-daily dosing and possibly escalating the dose to twice daily for a partial response to treatment. Those who do not have adequate relief after a 4- to 8-week PPI trial should undergo further testing before escalating the dose.[118,119]

Patients often inquire about adverse events from long-term PPI use. Most reports of adverse effects are from observational rather than randomized controlled studies.[6] The best evidence is for a slightly increased risk of worsening chronic kidney disease, *Clostridioides difficile* infection, and community-acquired pneumonia.[120–122] Some observational studies have also suggested that PPI use is a risk factor for osteoporosis, dementia, and gastric cancer, but the strength of this evidence is poor.[118,123,124]

Surgical Management

Antireflux surgery is indicated for patients who are intolerant of acid suppression, who are refractory to it, or who do not want to continue acid suppression in the long term. Two initial branch points when considering antireflux surgery are (1) the presence of obesity (BMI >35) and (2) the presence of a hiatal hernia. These conditions strongly predispose to reflux and influence its surgical decision-making, as detailed later in this chapter. For patients without obesity (BMI <35) or a large hiatal hernia, numerous treatment options are available that will be detailed in this section.

Operative Technique

Laparoscopic and robotic approaches have become the norm for antireflux surgery. Laparoscopy can be performed in the supine or French (low lithotomy) position, depending on surgeon preference, whereas robotic surgery is typically performed with the patient supine. Antibiotics and deep vein thrombosis (DVT) prophylaxis (unfractionated or low-molecular-weight heparin) are administered. Pneumoperitoneum can be achieved via a Veress needle or open technique. Steep reverse Trendelenburg positioning and a liver retractor enhance exposure of the hiatus. At least four ports (two for the surgeon, one for the camera, and one for the assistant) are used in addition to the liver retractor.

The hiatal dissection typically begins on the right crus by dividing the pars flaccida of the gastrohepatic ligament, noting any aberrant hepatic arteries. This plane is taken to the right crus, and then the right phrenoesophageal ligament is opened close to the crus and further opened anteriorly and posteriorly along the length of the crus. Care is taken to leave the diaphragmatic fascia on the crus to facilitate later closure and to stay close to the crus to avoid injuring nearby structures. This is followed by the left-sided dissection, which begins by dividing the short gastric vessels using an energy device, taking care to avoid thermal energy to the stomach and the spleen. This plane is carried around the fundus to the angle of His and then onto the left phrenoesophageal ligament, where the phrenoesophageal ligament is divided as it was on the right side. This dissection is typically taken anteriorly around the hiatus until it meets the right-sided dissection. After this, the esophagus is elevated anteriorly, and a tunnel is carefully made posterior to it. A Penrose is passed through this tunnel, around the esophagus, to retract the esophagus. To complete the circumferential dissection, the phrenoesophageal ligament dissection is continued posteriorly, connecting the left and right sides with a 360-degree clearance of the crura. If there is a hiatal hernia, the esophagus is mobilized in the mediastinum until at least 3 cm of intraabdominal esophageal length is obtained. The crura are closed posteriorly with interrupted permanent sutures, with or without pledgets depending on the surgeon’s preference and the strength of the crura, taking care not to narrow the esophagus. After this, the fundoplication is constructed. Of note, some surgeons begin with the left-sided dissection and then connect this to the right-sided dissection; this is simply a matter of surgeon preference (Fig. 83.15).

Three Hundred and Sixty-Degree Total (Nissen) Fundoplication

We pass a large (56 Fr) bougie to calibrate the diameter of the fundoplication. The fundus must be generously mobilized and passed posterior to the esophagus without becoming distorted or flipped upon itself. This can be accomplished by passing a grasper posterior to the esophagus to a suitable point on the fundus and then pulling this posterior to the esophagus. It is important to maintain the correct orientation of the fundoplication, keeping the greater curve cephalad—this can be identified as the cut edge of the short gastric vessels. To perform the “shoeshine maneuver,”

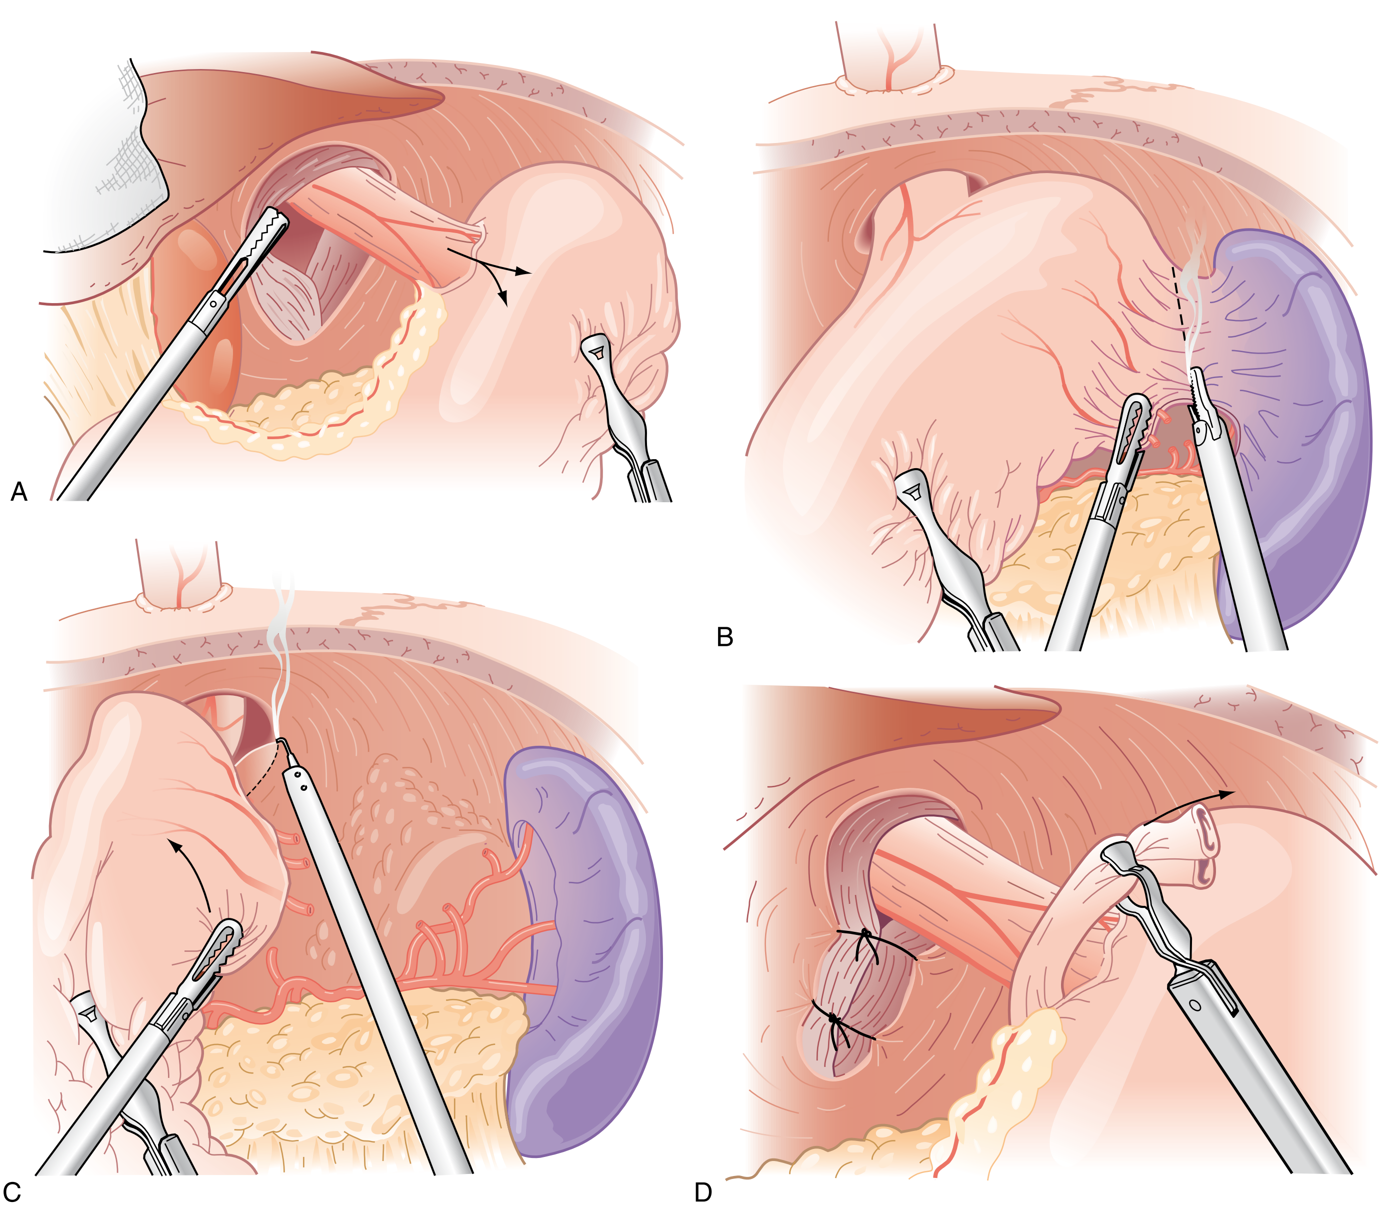

FIGURE 83.15 (A) The pars flaccida of the gastroesophageal ligament is opened onto the right crus, after which the phrenoesophageal ligament is opened. (B) To begin the left-sided dissection, the short gastric vessels are divided with an energy device. (C) The left-sided dissection is continued up to the phrenoesophageal ligament. (D) After the 360-degree mobilization is complete and an adequate length of esophagus is reduced into the abdomen, the crura are closed posteriorly with permanent suture.

the surgeon's left hand grasps the fundus that has been brought behind the esophagus, and the right hand grasps the proximal greater curvature, ensuring that there is enough fundus mobilized and that the two can be brought together anterior to the esophagus without tension. It is also intended to avoid too loose a fundoplication if the greater curvature of the stomach is grabbed too low. These are then sutured together with a permanent suture for a total length of 2 to 3 cm. Some surgeons suture the fundoplication to the esophagus to prevent slippage of the wrap. Some surgeons also place gastropexy sutures between the fundoplication and diaphragm to help prevent hiatal herniation (Fig. 83.16).

Partial Fundoplication

Partial fundoplications can be performed anteriorly (Dor fundoplication) or posteriorly (Toupet fundoplication). These partial fundoplications do not need to be performed over bougies because they are not circumferential. In a Toupet fundoplication, a shoeshine maneuver is performed similarly to a Nissen, but the fundus is sutured to the esophagus rather than to the fundus on the other side for a total of 240 to 270 degrees. The most cephalad sutures also incorporate the crura. A posterior suture from the wrap to the hiatal closure is also placed. A Dor fundoplication can be performed without dissecting the posterior attachments of the esophagus and without a shoeshine maneuver. It is performed by bringing the fundus over the anterior aspect of the esophagus and suturing it to the hiatus and esophagus (see "Achalasia" section).

Emerging evidence suggests that endoFLIP planimetry may help tailor the tightness of both complete and partial fundoplication. A postfundoplication distensibility index of 2.6 to 3.7 (for Toupet) and >2.2 (for Nissen) has been associated with decreased postoperative gas bloat and dysphagia and improved

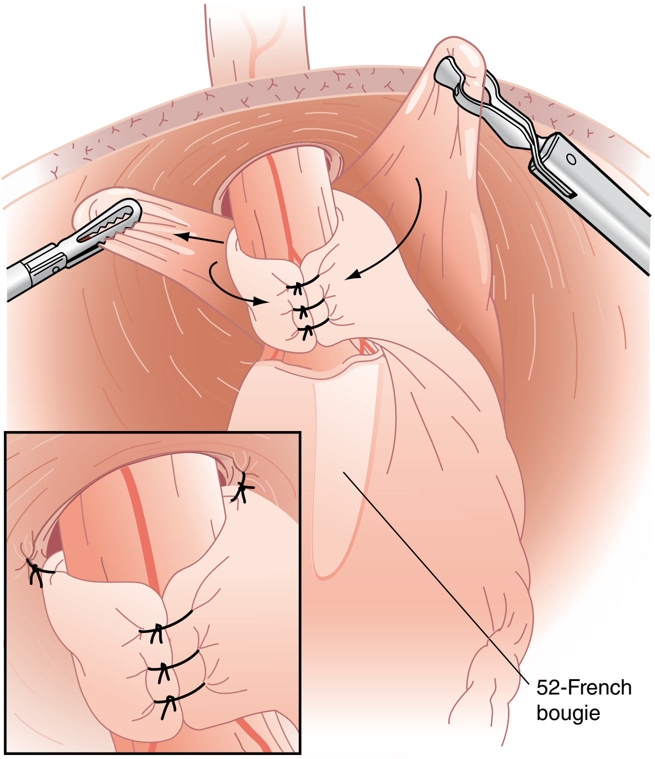

FIGURE 83.16 Completing the Nissen fundoplication with a "shoe-shine" maneuver followed by interrupted permanent sutures between both sides of the fundoplication. Additional sutures are sometimes placed to anchor the fundoplication beneath the diaphragm.

reflux control.[125,126] However, this has not been validated in RCTs and is not currently mainstream practice.

Multiple factors weigh into whether to perform a complete or partial fundoplication. Partial fundoplications are preferred in patients with esophageal dysmotility such as ineffective esophageal motility, as the partial nature of the wrap is thought to lead to less postoperative dysphagia. They are also preferred in the setting of a paraesophageal hernia (discussed later) because of the inability to obtain accurate preoperative manometry. A recent RCT compared the outcomes of Nissen and Toupet fundoplication and found equivalent reflux outcomes over a 3-year follow-up period, with slightly less dysphagia after Toupet in the short term.[127] Another recent RCT compared Nissen and Dor fundoplication over 15 to 20 years and found slightly improved reflux outcomes after Nissen but improved dysphagia and belching after Dor.[128] Multisociety consensus guidelines published in 2023 favor partial fundoplication over complete fundoplication because of decreased hiatal hernia recurrence, dysphagia, and inability to belch, with only a modest difference in long-term reflux control; this is a "conditional" recommendation based on "moderate" evidence.[129] Overall, the approach should be tailored to each individual patient's anatomy, physiology, and goals for surgery (Fig. 83.17).

Outcomes of Fundoplication

Short-term complications are rare, with perioperative mortality rates approaching 0.1% and the risk of bleeding, infection, and gastric or esophageal perforation approximately 1% each. Severe dysphagia with inability to manage oral secretions mandates immediate surgical revision. Mild to moderate short-term dysphagia is common but typically self-limited.[130] Patients are typically maintained on a full liquid diet at least a week after surgery, followed by gradual advancement to a pureed and then soft diet.

Long-term outcomes from laparoscopic fundoplication are overall good, with the vast majority of patients experiencing durable symptom control and objective decrease in acid exposure. Patient satisfaction after both Nissen and Toupet fundoplication approaches 90%.[128] However, several complications are worth noting.

- Dysphagia—The presence of dysphagia in the first few months after antireflux surgery may be as high as 50%, but this typically resolves on its own as edema and inflammation subside.[130] Patients who still can tolerate liquids should be maintained on a full liquid diet initially. Dysphagia persisting for over 3 months after antireflux surgery should be investigated with a barium swallow. This may be caused by hiatal herniation, an overly tight hiatal closure, or a malformed fundoplication. Endoscopic dilations may help address a wrap or hiatal closure that is too tight. However, hiatal herniation of the fundoplication often requires revisional surgery.[131]
- Gas bloat—Fundoplication diminishes the ability to belch and vent air from the stomach, more so with Nissen fundoplication than partial fundoplication. This can lead to a "gas bloat" syndrome. This may be treated with behavioral modification such as avoiding carbonated beverages and eating slowly. Gas-dissolving agents such as simethicone may also be helpful. However, if this does not resolve over time, additional studies can be done to assess these symptoms, including a gastric emptying study, which can be done to rule out postoperative gastroparesis, which may be the result of a vagal nerve injury.
- Recurrent GERD—Some degree of symptomatic recurrence may occur in a substantial share of patients. This often responds to acid suppression, and 20% to 40% of patients have resumed PPI use at the 15- to 20-year mark after surgery.[128,132]
- Wrap failure—Fundoplications can become structurally disrupted in various ways. The most common etiology of fundoplication failure is hiatal herniation of the wrap. All postoperative hiatal hernias are not clinically relevant, but some may cause bothersome reflux and/or dysphagia. The fundoplication can also become completely or partially undone over time.[133]

Horgan et al. published a classification of fundoplication failures in 1999 that remains relevant today when evaluating suspected anatomic failures (see Fig. 83.16). According to this study, type IA failures (herniation of the GEJ and fundoplication) most often caused heartburn with or without a component of dysphagia, but other types of failures (e.g., type IB, herniation of the GEJ; type II, herniation of the fundoplication only; or type III, malpositioned fundoplication) were frequently associated with dysphagia only[131] (Fig. 83.18).

The long-term reoperation rate after fundoplication is 5% to 7%, primarily because of recurrent GERD symptoms and/or persistent dysphagia.[134,135] Patients presenting for revisional surgical evaluation should be comprehensively evaluated with manometry and ambulatory pH monitoring, EGD, and a barium swallow. The threshold to reoperate should be higher than to perform primary surgery given the increased technical difficulty of reoperative surgery and resultant complication rate and the increased likelihood that an alternate issue (e.g., dysmotility or hypersensitivity) may be underlying the patient's symptoms. Patient satisfaction decreases with each surgical attempt, from 91% at the primary operation to 76% at the first reoperation and 49% at the second reoperation.[136]

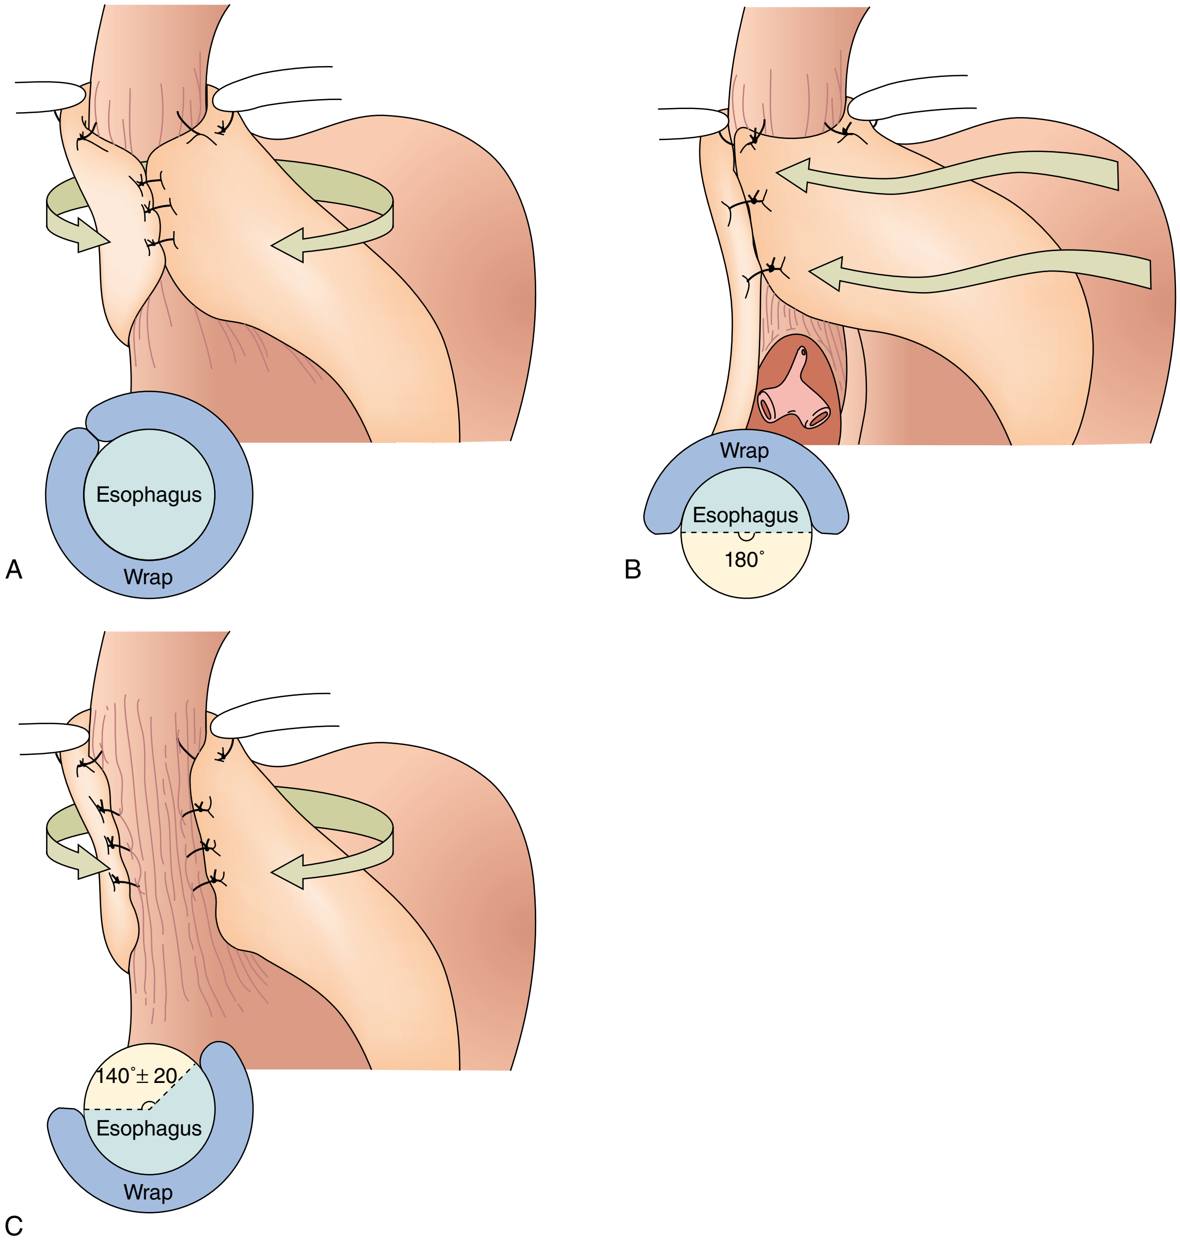

FIGURE 83.17 Three types of fundoplication. (A) 360-degree (Nissen) fundoplication. (B) Partial anterior (Dor) fundoplication. (C) Partial posterior (Toupet) fundoplication.

In 2012, the FDA approved the Linx (Ethicon) magnetic sphincter augmentation (MSA) device as an alternative surgical treatment for medically refractory reflux, with the promise of simpler, more reproducible surgical technique and fewer side effects than fundoplication. The device has a "Roman Arch" design that, when sized appropriately, does not exert any compressive force on the esophagus when the device is in the closed position. When closed, the magnetic force is highest, but the beads exert this force on each other rather than on the esophagus. When a food bolus passes, the ring expands and the magnetic force between the beads decreases to permit bolus passage (Fig. 83.19).

The device is recommended for use in patients with grade A or B esophagitis, no hiatal hernia larger than 3 cm, BMI less than 35, and adequate esophageal motility, defined as distal wave amplitude greater than 35 mm Hg and greater than 70% effective swallows. It is not indicated for patients with paraesophageal hernias, grade C or D esophagitis, Barrett esophagus, dysphagia or inadequate esophageal motility, or the need for MRIs greater than 1.5 Tesla. Indications with emerging clinical evidence include the use of MSA rather than fundoplication in paraesophageal hernias and in patients with reflux status post sleeve gastrectomy, who do not have a fundus with which to perform fundoplication. Observational studies suggest reflux improvement and acceptable safety in these populations, but they have not been tested in RCTs against the standard of care.

The surgical technique for Linx implantation begins similar to that of fundoplication, typically involving full dissection of the hiatus and GEH, without taking down the short gastric vessels. If a hiatal hernia is noted, it must be repaired. After this, a tunnel is created between the posterior vagus nerve and the esophagus, and a sizing device is placed circumferentially around the esophagus through this tunnel, incorporating the anterior vagus but leaving

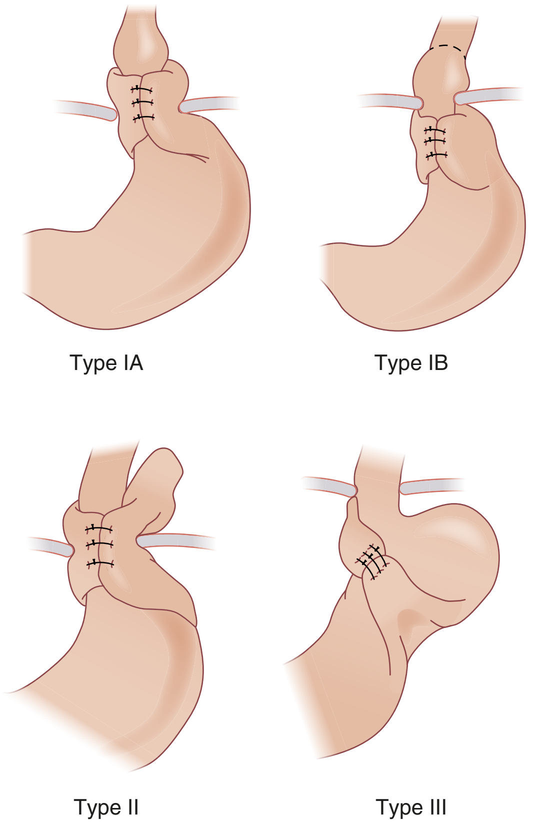

FIGURE 83.18 Horgan et al.'s classification of fundoplication failures. Type IA hernia: The gastroesophageal junction and the wrap are above the diaphragm. Type IB hernia: The gastroesophageal junction is above the diaphragm. Type II hernia: Paraesophageal herniation of the top of the fundoplication. Type III hernia: Malformation of the wrap. The body of the stomach is used to perform the fundoplication. (From Horgan S, Pellegrini CA. Surgical treatment of gastroesophageal reflux disease. *Surg Clin North Am*. 1997;77:1063-1082.)

out the posterior vagus nerve. Once appropriately sized, the device is then placed around the esophagus via a 10-mm port. A "minimal dissection technique" is described in which a full dissection of the GEJ is not performed, instead creating a tunnel posterior to the esophagus through the periesophageal connective tissues. This technique is not favored because it may miss hiatal hernias and worsen outcomes.[137]

Reflux control with MSA appears to be superior to that of PPI—particularly for regurgitation symptoms—in the short term based on a single RCT.[138] When compared with Nissen fundoplication, MSA appears to have a slightly better side effect profile but is not superior to fundoplication based on the available observational data. There are no randomized trials comparing MSA with fundoplication, but a recent meta-analysis of 19 observational studies suggests similar reflux control with both procedures and fewer gas-bloat symptoms with MSA. Of 12,697 patients undergoing MSA in this analysis, 3.3% required device removal due to complications.[139] The most feared complication of MSA is device erosion into the esophagus, which may occur in up to 0.3% to 1% of patients typically 1 to 4 years after placement.[137,140] Device undersizing appears to be a risk factor for erosion, as it causes greater compression of the esophageal tissue. Cost is also a concern with MSA; the Linx device costs $5000 to $6000 per use, which may be borne by the hospital rather than the insurer.[141]

Endoscopic Management

Though antireflux surgery is the gold standard for medically refractory GERD, endoscopic procedures are emerging in popularity for appropriately selected patients who want a less invasive option. Endoscopic approaches are generally recommended only for patients who do not have severe reflux esophagitis (LA grades C or D), hiatal hernias >2 cm, obesity, or severe GERD symptoms.

Transoral Incisionless Fundoplication

Transoral incisionless fundoplication (TIF) is the predominant endoscopic option[129] (Fig. 83.20). It is performed endoscopically,

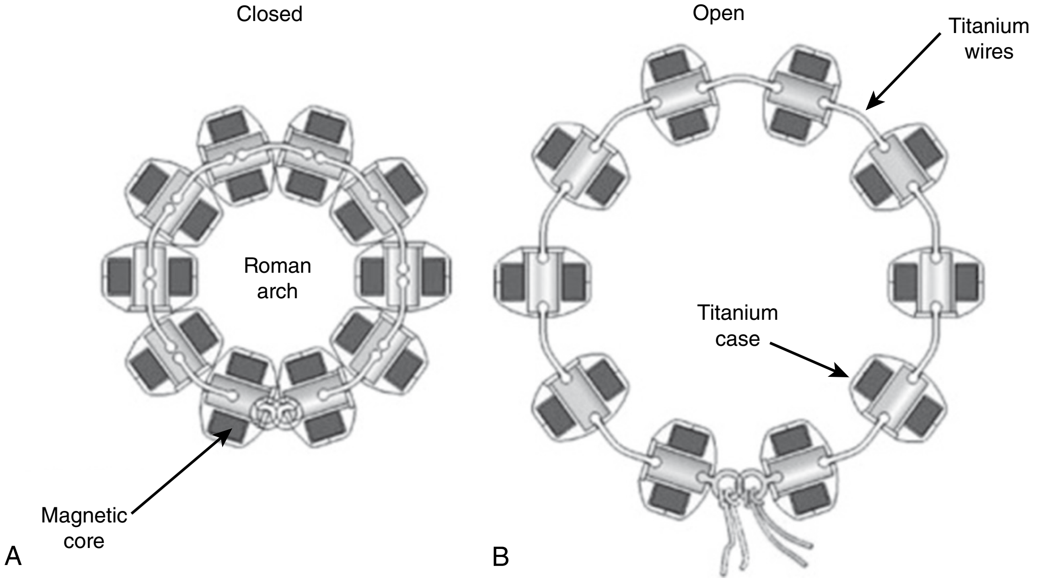

FIGURE 83.19 The Linx magnetic sphincter augmentation device. (A) Illustration of closed implant. (B) Illustration of open implant.

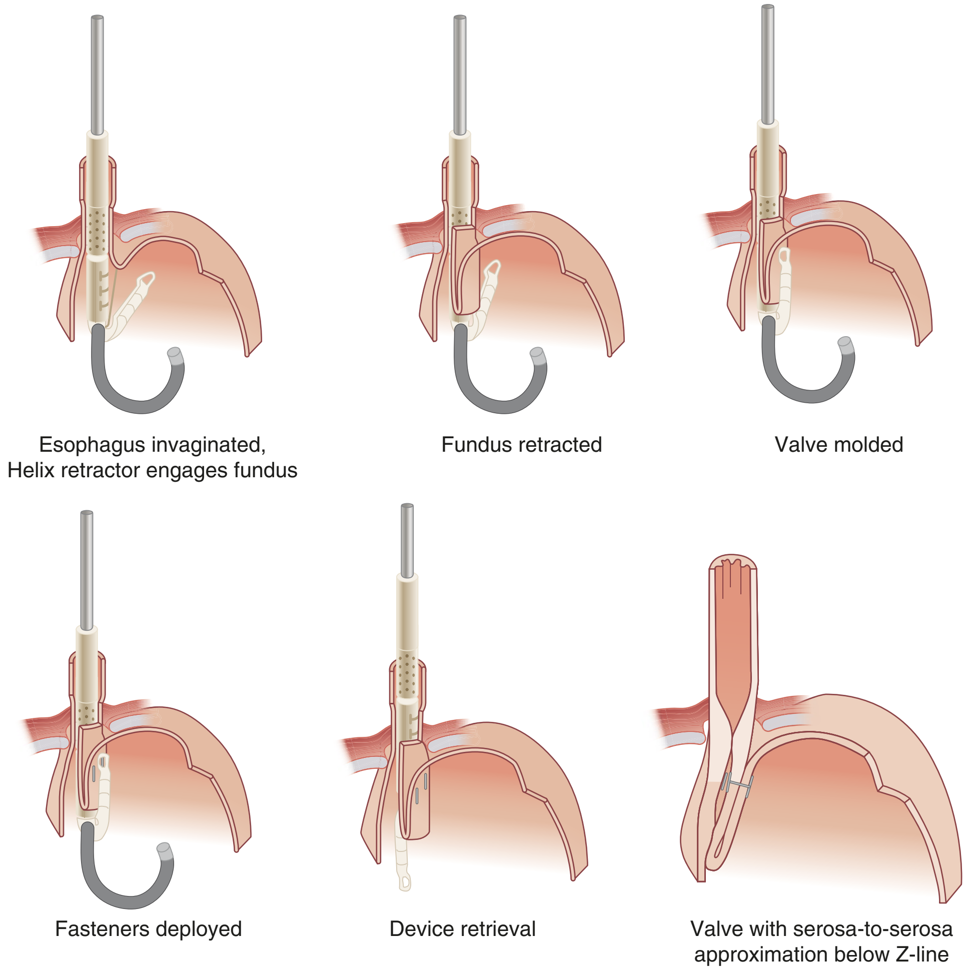

FIGURE 83.20 Illustration of the TIF 2.0 procedure (EndoGastric Solutions).

using one of two systems: the EsophyX device (EndoGastric Solutions, Redmond, WA) or Xylo Technologies system. Of these, the EsophyX TIF 2.0 device has the largest body of supporting evidence and has supplanted the TIF 1.0 technique first published in 2008. The EsophyX is an over-the-scope device that uses a helical retractor to pull the fundus into the gastric lumen, then deploys polypropylene H-fasteners between the fundus and esophageal lumen. These are carried circumferentially to create a 270-degree, 3-cm fundoplication. The technique requires general anesthesia and two skilled operators. TIF 2.0 has a 2.4% rate of severe complications, including perforations, bleeding, and pneumothorax.[142] In terms of outcomes, TIF 2.0 has shown superiority to PPI for subjective and objective reflux resolution in multiple RCTs.[142–146] However, evidence comparing TIF 2.0 to fundoplication is lacking, leading the most recent multispecialty consensus guidelines to favor fundoplication over TIF 2.0.[129] TIF may have a role in treating medically refractory heartburn or regurgitation in patients who wish to avoid surgery and do not have contraindications to endoscopic management.[129,147] It bears noting that some patients may have persistent symptoms after TIF, and performing a surgical fundoplication after TIF can be challenging.

The MUSE system consists of an endoscopic stapling device coupled with an ultrasound transducer. The technique involves retroflexing an endoscope within the stomach, with the stapler at the tip used to push the fundus toward the esophagus, where the ultrasound confirms correct alignment of the fundoplication. Staples are serially fired until an anterior fundoplication is created. Outside of small observational studies, evidence comparing MUSE with other antireflux treatment is lacking, and this procedure is not widespread in the United States.[148–150]

Stretta

Stretta (Mederi Therapeutics, Norwalk, CT) is another endoscopic antireflux device that delivers radiofrequency energy to the distal esophagus, thickening the muscular tissue, increasing LES pressure, and decreasing transient relaxations. Based on inconsistent efficacy, guidelines currently favor fundoplication over Stretta based on superior reflux control and patient satisfaction. According to the most recent guidelines of the American Gastroenterological Association, Stretta should not be considered in any scenario of PPI-refractory cases.[129,147]

Gastroesophageal Reflux Disease and Obesity

Obesity and reflux are deeply intertwined. For one, obesity is a key factor in the pathogenesis of GERD: Obesity increases intraabdominal pressure, thus augmenting the transdiaphragmatic pressure gradient driving GERD. Obesity is associated with increased GERD severity as well as rates of esophagitis and esophageal and gastric adenocarcinoma. This has numerous mechanisms, outlined earlier, including an increase in transient LES relaxations and, most notably, an increase in intraabdominal pressures exacerbating the transdiaphragmatic pressure gradient.[151] As such, GERD treatment—particularly antireflux surgery—in patients with obesity must account for and ideally treat obesity concurrently. Conversely, obesity treatment—particularly bariatric surgery—can exacerbate or improve underlying GERD, and as such, bariatric surgery decisions must account for preexisting GERD. Approaching GERD or obesity in isolation can lead to untenable patient outcomes. This section reviews these complex decisions in detail.

Obesity and Antireflux Surgery

Obesity can dramatically affect the success of antireflux surgery. The mechanisms for this are simple: First, obesity increases intraoperative technical difficulty by impeding visualization and tissue manipulation, and foregut surgery is no exception. Second, a fundoplication may only add 3 to 10 mm Hg to GEJ pressures, as a fundoplication must balance reflux control with dysphagia.[152,153] However, this may not be enough to overcome the large increase in intraabdominal pressure seen in obesity, which may be 15 to 20 mm Hg higher than nonobese controls.[151,154] Further, high intraabdominal pressure predisposes to hiatal hernia recurrence, another key risk factor for recurrent postoperative GERD.

For these reasons, performing a fundoplication as antireflux surgery in obese patients is at best controversial. Laparoscopic Roux-en-Y gastric bypass (RYGB) may be the optimal antireflux operation in obese patients for multiple reasons. First, anatomically, the short gastric pouch has few acid-producing parietal cells and the length of the Roux limb protects against bile reflux. Second, significant weight loss reduces the intraabdominal pressure driving GERD as well as technical failures of antireflux surgery such as wrap slippage and hiatal herniation.[155,156] Finally, unlike fundoplication, RYGB addresses metabolic comorbidities and in turn reduces all-cause mortality in patients with obesity.[157] A SAGES Foregut Task Force White Paper from 2020 stated that in patients with BMI >35, "RYGB is the [antireflux] procedure of choice for patients with GERD."[158] However, patients who undergo gastric bypass have a 10% to 30% risk of ongoing reflux symptoms or need for ongoing antireflux medications.[159–165] They also risk long-term complications including marginal ulceration, dumping syndrome, and internal hernias. Some patients are not good candidates for RYGB or may be unwilling to undergo such a complex procedure. As such, a subsequent multisociety consensus guideline softened the recommendation for RYGB, stating that patients with reflux and BMI >35 should be offered the choice between fundoplication and RYGB, but that with BMI >50, RYGB only should be offered as an antireflux procedure.[129]

Gastroesophageal Reflux Disease and Bariatric Surgery

Among patients seeking bariatric surgery, 20% to 40% may have preexisting GERD.[166] Bariatric surgery confers numerous benefits to patients' quality and quantity of life, but it may worsen GERD in a subset of patients. This section reviews best practice in evaluating, preventing, and managing GERD around bariatric surgery.

Preoperative Evaluation

A history inquiring about upper GI symptoms before proceeding with bariatric surgery is essential. However, as 20% of asymptomatic patients may have "silent" esophagitis and up to 40% may have abnormal acid exposure on pH monitoring, history alone is an insensitive screening test for GERD.[166–168] Many programs routinely use some form of objective evaluation before proceeding with bariatric surgery, but this is by no means universal. Given the prevalence of esophagitis and other upper GI abnormalities in the bariatric population, the American Society for Metabolic and Bariatric Surgery states that "routine preoperative EGD is justifiable and should be done at the surgeon's discretion."[166] The gold standard for GERD detection would be ambulatory pH monitoring, but this is rarely routinely employed and generally reserved for patients with severe symptoms.

Surgical Decision-Making

Sleeve gastrectomy has rapidly become the most common bariatric operation in the United States, now accounting for 70% of bariatric operations.[169] It has supplanted RYGB in popularity because of its superior safety and similar weight loss. However, its most common persistent complication is new or worsening GERD in as many as 30% of patients, and this is the most important determinant of postoperative patient satisfaction.[159,160,170,171] Mechanisms for this include alterations to the angle of His and gastric sling fibers that decrease LES pressure as well as the high intragastric pressure generated by a narrow tubular stomach.[172,173] Postoperative strictures, which generally occur at the incisura angularis, further increase intragastric pressure and predispose to reflux.

Though a detailed review of sleeve gastrectomy technique is outside the scope of this chapter, there is reasonable evidence that aspects of bariatric surgery technique may influence the development of postoperative GERD. Fully dissecting the hiatus, identifying and repairing hiatal hernias posteriorly, and excluding the fundus at the time of sleeve gastrectomy are associated with decreased postoperative GERD.[174,175] For gastric bypass, a small pouch, fully excluded fundus, and adequate (>100 cm) Roux limb appear protective against GERD.[155,176] Post–sleeve gastrectomy GERD is complex and unpredictable; many patients in fact enjoy improvements in GERD after significant weight loss. However, numerous studies have shown that when compared with sleeve gastrectomy, RYGB has a superior impact on GERD outcomes, and as such, it is the bariatric operation of choice in patients with medically refractory reflux.[129,158–160,171] However, given its long-term complication profile, some patients with GERD and obesity are not good candidates for RYGB, and bariatric decision-making in these cases needs to be individualized for each patient.

Managing Post–Bariatric Surgery Gastroesophageal Reflux Disease

As in the general population, behavioral modification and PPIs are the initial management of postoperative reflux. However, for refractory symptoms, we recommend a comprehensive workup akin to that of any patient considering antireflux surgery, including upper GI, EGD, pH monitoring, and esophageal manometry. In fact, the American Society for Metabolic and Bariatric Surgery (ASMBS) conditionally recommends routine EGD 3 to 5 years after sleeve gastrectomy to screen for Barrett esophagus even in asymptomatic patients.[166] This evaluation is needed to prove the diagnosis of GERD, identify complications of GERD, and assess for related pathology such as hiatal hernias and esophageal dysmotility.

Patients who have undergone sleeve gastrectomy cannot receive fundoplication, as they no longer have a fundus. The gold standard treatment for severe GERD in patients who have undergone sleeve gastrectomy is conversion to RYGB.[129,155,161,164] There is interest in revisional antireflux options that do not carry the risks of RYGB. If a hiatal hernia is present, some surgeons simply repair the hernia. Several small single-arm studies suggest this may be effective for several years.[177–179] MSA has also been used in the post–sleeve gastrectomy population, with a subjective response rate of 80.8% at 1 year.[180] However, the long-term durability of these approaches is unknown, and they are less likely to be effective in patients with BMI >35.

Patients with reflux after RYGB have few revisional options. Given the numerous antireflux mechanisms of RYGB, it is essential to objectively confirm the diagnosis of GERD in these patients using pH monitoring before considering revisional surgery. If patients with confirmed GERD have a significant hiatal hernia, repairing this may address symptoms. Fundoplication using the fundus of the remnant stomach has been described but is not mainstream practice. MSA has been employed in post-RYGB patients but has much less supporting evidence than post–sleeve gastrectomy.[181]

Gastroesophageal Reflux Disease and Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) is a chronic and progressive form of usual interstitial pneumonia of unknown origin that leads to pulmonary fibrosis. IPF affects about 40,000 individuals every year in the United States. Median survival after the diagnosis is established is between 3 and 5 years, with approximately 80% of all deaths caused by respiratory failure. Because pharmacologic therapy is mostly ineffective, lung transplantation offers the only chance of survival.

Although the pathogenesis of this disease is probably multifactorial, there is evidence today that GERD might play a role in the genesis and/or progression of the disease through repeated episodes of microaspiration of gastric contents.

GERD is quite common in patients with IPF, with pH monitoring showing high rates of pathologic reflux: between 60% and 70% in the distal esophagus and 30% and 50% in the upper esophagus.[182,183] Esophageal manometry has shown that in patients with IPF, the LES is often hypotensive and esophageal peristalsis abnormal.[184] A hiatal hernia is frequently present and associated with a higher reflux score. In addition, an increased transdiaphragmatic pressure gradient caused by a more negative intrathoracic pressure might contribute to gastroesophageal reflux.[154,185] These findings suggest that patients with IPF are at high risk of aspiration of gastric contents.

Although the findings of these studies show a high prevalence of pathologic reflux in patients with IPF and potential for aspiration of gastric contents, the relationship of GERD and IPF is still uncertain, as it is not clear if these two diseases are independent from each other or if GERD contributes to the genesis and progression of IPF. This is of key importance, as it would influence both the diagnostic evaluation and treatment: Specifically, would the treatment of the abnormal reflux influence the progression of the disease?

Considering the elements that play a role in causing the abnormal reflux, it is doubtful that PPI can be an effective treatment, as it is known that although they can suppress the acid production by the parietal cells, therefore changing the pH of the refluxate, they are not able to stop the reflux through an incompetent LES. Only a fundoplication, by restoring the competence of the LES, can control any type of reflux, acidic or nonacidic.

As of today, there are only a few retrospective studies in the literature that have assessed the effect of antireflux treatment in patients with IPF and GERD. For instance, Lee et al. assessed the effect of antireflux treatment—PPI or Nissen fundoplication—in a large cohort of patients with IPF.[186] The study cohort consisted of 204 patients with IPF from the University of California San Francisco and the Mayo Clinic in Rochester. Mean forced vital capacity (FVC) was 69% predicted, and the diffusing capacity for carbon monoxide (DLCO) was 47% predicted. Eighty-six patients were treated with PPI and 17 with H2-blocking agents. Eleven patients had a Nissen fundoplication. The study showed that use of acid-reducing medications or laparoscopic antireflux surgery (LARS) was associated with lower high-resolution CT fibrosis score and longer survival time in patients from both institutions, suggesting that gastroesophageal reflux and microaspiration may play an important role in the pathobiology of IPF.

To properly test the hypothesis that treatment of GERD in IPF could change the natural history of the disease by altering the progression, a prospective, randomized trial was designed—the WRAP-IPF trial.[187] In this phase II NIH trial, patients with IPF and GERD were recruited from six academic centers in the United States. The enrolled patients had abnormal acid exposure by 24-hour pH monitoring and preserved FVC. The primary end point was change in the FVC from randomization to week 48. Twenty-nine patients were randomly assigned to receive surgery and 29 to no surgery (treated with PPIs). All patients tolerated the LARS well with no complications. The results showed that there was no difference between the two groups in terms of FVC. Acute exacerbations, respiratory-related hospitalizations, nonelective hospitalization, and lung transplantation were less common in the surgery group but without statistical significance. In summary, this long-awaited controlled trial in patients with IPF and GERD showed that LARS was safe and well tolerated and suggested that antireflux surgery significantly did not slow the rate of FVC decline.[187] Unfortunately, a careful analysis of the methods and the results shows that this study had many severe flaws that compromise the validity of the conclusions: The study was very underpowered, as 400 patients rather than 58 were required to achieve 90% power. In addition, the effect of LARS on FVC decline and clinical events in patients with IPF and GERD might have been reduced by the near-universal use of antiacid medications in the nonsurgery group. Finally, when the authors did a post hoc exploratory analysis of the primary end point using Lachin worst rank analysis (an approach that assumes that missing values are informative and reflect poor outcomes), the difference between groups was significant ($p = 0.017$) and favored the surgical group.

Recently a bidirectional two-sample Mendelian randomization study demonstrated that GERD increases the risk of IPF but found no evidence that IPF increases the risk of GERD.[188] In addition, abnormal bolus reflux on impedance pH testing is associated with decreased time to poor pulmonary outcomes and death.[189]

Overall, these studies suggest that there is a subgroup of patients with IPF in whom pathologic reflux is documented who might benefit from antireflux therapy, particularly before a lung transplant: These are patients in whom proximal reflux is documented by pH monitoring or impedance, and pepsin or bile acids are detected in the bronchoalveolar lavage fluid (BALF), suggesting that aspiration of gastric contents is occurring. These patients might benefit from fundoplication before their functional status deteriorates.

HIATAL AND PARAESOPHAGEAL HERNIAS

Hiatal hernias have an important association with GERD; identifying and repairing these are key components of antireflux surgery. Paraesophageal hernias, a subset of hiatal hernias, are often themselves an indication for surgery, with unique symptomatology, evaluation, and treatment considerations (Fig. 83.21).

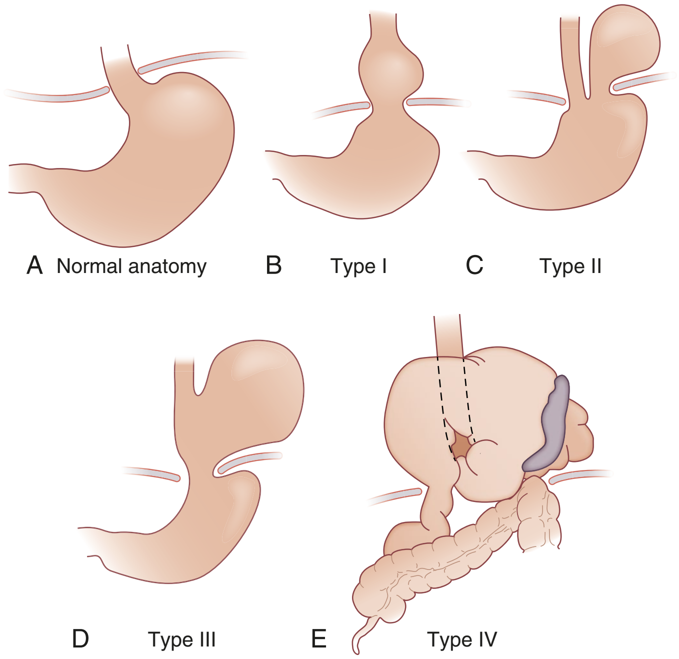

FIGURE 83.21 Hiatal hernia types. (A) normal anatomy. The stomach is completely in the abdomen. (B) Type I: esophagogastric juntion is above the diaphragm. (C) Type II: esophagogastric juntion is in the abdomen but the gastric fundus is herniated. (D) Type III: both esophagogastric juntion and the gastric fundus are herniated. (E) Type IV: another organ apart from the stomach is also herniated.

Classification and Pathophysiology

In normal anatomy, the GEJ and the entire stomach lie within the abdomen, below the diaphragmatic hiatus. Hiatal hernias are classified as follows, with type II, III, and IV considered "true" paraesophageal hernias. Overall, hiatal hernias may be present in 10% to 15% of adults based on radiologic studies.[190]

- *Type I* (aka "sliding" hiatal hernia)—The GEJ migrates through the hiatus into the mediastinum. These are the vast majority (70%–90%) of all hiatal hernias and may not be clinically significant unless they are associated with severe GERD or other symptoms.
- *Type II* —The fundus migrates into the mediastinum, but the GEJ remains intraabdominal. These are uncommon.
- *Type III* —The GEJ and a portion of the stomach have herniated. These are the most common "true" paraesophageal hernias.
- *Type IV*—The stomach and another intraabdominal organ (typically colon, pancreas, omentum, or spleen) form the hernia contents.

Hiatal hernias result from laxity of the diaphragmatic crura and the phrenoesophageal ligaments. They likely progress in part because of the transdiaphragmatic pressure gradient; as such, they are more common in patients with high intraabdominal pressure (e.g., obesity, weightlifters) and low intrathoracic pressure (e.g., chronic pulmonary disease). They are more common in females and with increasing age.[190,191]

Clinical Presentation

Because the diaphragmatic crura are a key component of the GEJ antireflux barrier, hiatal hernias (particularly sliding hernias) contribute to the development of GERD, esophagitis, and Barrett esophagus.[192] The prevalence of hiatal hernias may be as high as 75% in patients with objectively confirmed GERD.[193] Moreover, hiatal hernias may cause symptoms that do not resolve with acid suppression, such as regurgitation or dysphagia.

True paraesophageal hernias do more than undermine the antireflux barrier; they may compress the GEJ or the stomach and cause obstructive symptoms such as dysphagia, early satiety, pain, regurgitation, and/or bloating. They also have numerous non-GI implications. Paraesophageal hernias may cause dyspnea and pulmonary complications because of mass effect, cardiac compression, and/or microaspiration, which improve after repair.[191,194,195] They are also associated with anemia in 30% to 40% of patients; chronic gastric compression can lead to ischemic "Cameron ulcers" that resolve when the hernia is repaired.[196] Rarely, a paraesophageal hernia can cause acute gastric volvulus, resulting in obstruction, ischemia, and possible gastric perforation.

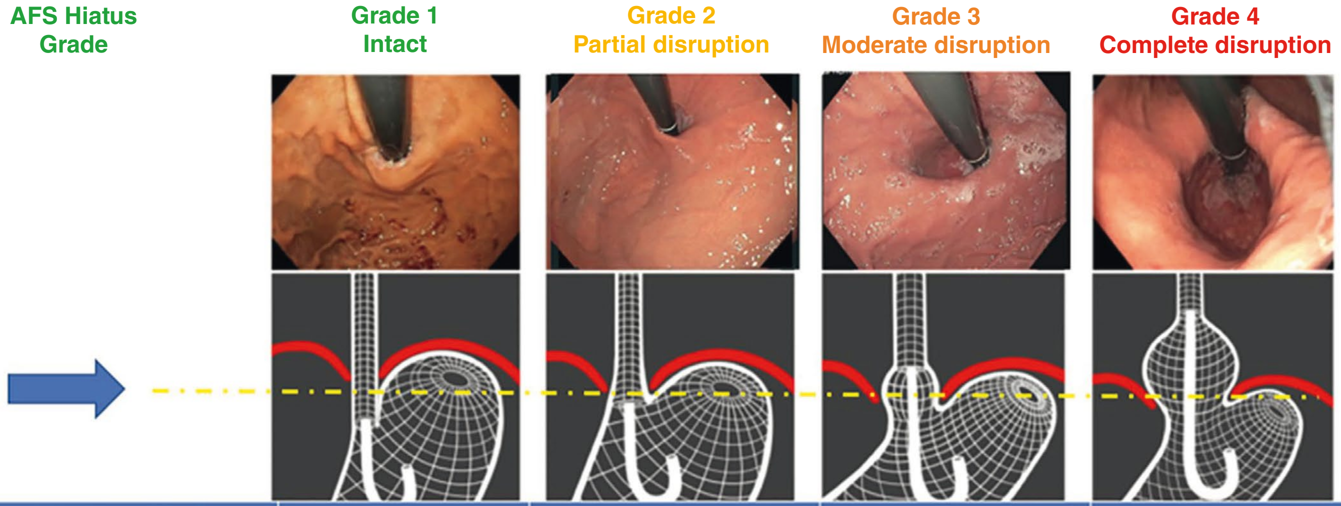
Evaluation and Decision-Making

When patients present for surgical consultation regarding a hiatal hernia, the initial history and physical are like those for GERD. Often the hiatal hernia is identified during the preoperative evaluation for GERD. In addition to these symptoms, surgeons should inquire about non-GI symptoms outlined earlier. Patients with paraesophageal hernias are often more frail and elderly than the typical general surgical population, so specific attention should be paid to cardiopulmonary risk factors and exercise tolerance. However, laparoscopic paraesophageal hernia repair remains safe even in these populations.

In terms of diagnostic workup, hiatal hernia is typically identified during an EGD or imaging such as CT scan or barium swallow. Chest x-ray may sometimes identify a large hernia, but it needs to be followed with dedicated imaging. Barium swallow does provide the highest degree of detail regarding the anatomy of the hernia and the presence of associated pathology (e.g., esophageal webs, strictures, dysmotility) but is not necessarily required if CT imaging clearly shows a large paraesophageal hernia. Upper endoscopy is strongly recommended before surgery to assess for mucosal pathology. The degree and size of herniation are assessed in retroflexion after the stomach is fully insufflated. Historically, the Hill grading system was used to classify the GEJ flap valve. In 2023 the American Foregut Society Endoscopic Classification of Esophagogastric Junction Integrity was described, and time will tell if this is more broadly adopted (Fig. 83.22).[197]

Additional testing such as esophageal manometry and ambulatory pH monitoring may be useful in patients with sliding hiatal hernias but is not necessary in patients with true paraesophageal hernias. Esophageal manometry is particularly unreliable with large paraesophageal hernias, and some degree of dysmotility should be presumed in these patients.

All sliding hiatal hernias do not require surgery; they should only be repaired if patients otherwise qualify for antireflux surgery (or bariatric surgery) based on objective physiologic testing and symptoms that persist after maximal medical therapy. Historically, all paraesophageal hernias were thought to require surgery, regardless of symptoms, based on the risk of acute gastric volvulus causing catastrophic outcomes. However, the risk of acute volvulus is low, currently estimated at 1% per year, and operative mortality after emergency repair is lower than previously thought—5.4% based on Nationwide Inpatient Sample data.[198] As such, paraesophageal hernia repair is currently recommended only for patients with associated symptoms or complications. Paraesophageal hernias may only cause atypical or subtle symptoms, though, and up to 90% of patients may disclose symptoms when carefully questioned.[199] Repair in asymptomatic patients remains



AFS Hiatus Grade
Grade 1 Intact
Grade 2 Partial disruption
Grade 3 Moderate disruption
Grade 4 Complete disruption

The "L" within the LDF components represents the hiatal hernia length, measured in centimeters between the Z line and the diaphragmatic pinch. The "D" represents the largest diameter of the hiatus measured in centimeters with 1 conventional scope diameter being approximately 1 centimeter; and the "F" represents the presence (F+) or absence (F−) of the gastroesophageal flap valve. (From Del Grande LM, Herbella FAM, Katayama RC, Schlottmann F, Patti MG. The role of the transdiaphragmatic pressure gradient in the pathophysiology of gastroesophageal reflux disease. *Arq Gastroenterol.* 2018;55[Suppl 1]:13-17.)

controversial and may be offered based on shared decision-making and patient fitness for surgery.[200]

Surgical Treatment

In current practice, laparoscopic and robotic transabdominal approaches dominate the treatment of paraesophageal hernia. Transthoracic approaches make up 2% or less of paraesophageal hernia repairs and will not be discussed here.[201] Positioning and setup for paraesophageal hernia resemble that of other antireflux operations; the authors' preferred port placement is illustrated in Fig. 83.23.

The surgical approach begins like that of fundoplication described earlier in this chapter. After obtaining laparoscopic access to the peritoneum and positioning the patient in steep reverse Trendelenburg, we reduce the hernia contents with manual traction and attempt to decompress the stomach via an orogastric tube. We then enter the lesser sac with an energy device either on the right (via the pars flaccida) or the left (via the short gastrics). Once this plane is carried to the crura, the key maneuver is to develop the plane between the hernia sac medially and the crura laterally. When done precisely, the fascia overlying the crura is left intact to facilitate crural closure, and the sac is divided close to the crura. This plane is carried circumferentially, first anteriorly to the opposite crus, until the sac is largely reduced into the abdomen. Though not intended, and especially during recurrent repairs, the pleural space may end up being opened, but this is generally inconsequential because the patient is being ventilated with positive pressure and the CO_2 used for insufflation absorbs rapidly. If the patient has respiratory issues, the pleural tear can be enlarged to equalize the pressure with the abdomen, the insufflation pressure can be temporarily decreased, and the anesthesiologist can increase the respiratory rate to address CO_2 retention. After the sac is mobilized anteriorly, we typically carry the dissection posterior to the esophagus, encircling the esophagus with an elastic drain to facilitate retraction. The sac's attachments to the pleura and mediastinum must be completely mobilized out of the chest with blunt dissection or an energy device, and the esophagus is also fully mobilized. Excision of the hernia sac is important because its bulk may interfere with subsequent fundoplication or serve as a lead point for reherniation; however, one must take care not to injure the vagi, esophagus, or stomach during this step. As the stomach and esophagus are reduced into the abdomen, the vagus nerves will enter the field and must be identified and protected. We continue dividing attachments of the esophagus to the mediastinum until we obtain at least 2 to 3 cm of intraabdominal esophageal length off tension. This dissection can be carried up to the pulmonary veins or even the aortic arch if necessary; laparoscopic visualization is typically excellent and can be enhanced with a 0-, 30-, or even a 45-degree scope to look high in the mediastinum.

Hiatal Closure

Once we have adequate esophageal length, we proceed with hiatal closure. Numerous techniques exist for hiatal closure: interrupted, running, figure-eight, and mattress patterns are all used, with

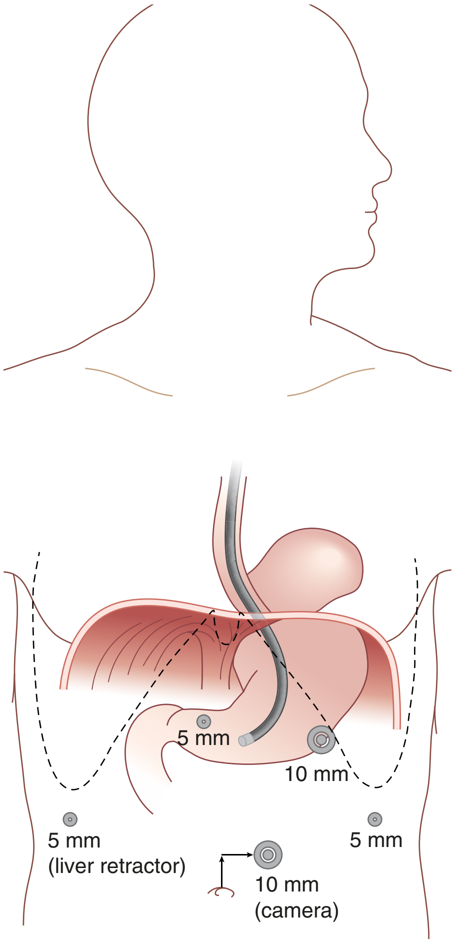

FIGURE 83.23 The authors' preferred port placement for paraesophageal hernia repair.

braided permanent sutures, which can be placed intracorporeally, using a free needle, Endo-Stitch, or extracorporeal knot-tying system. We generally use double pledgeted 0-Ethibond suture in an interrupted suture pattern. No suturing technique has proven superior to any other, but a posterior repair with permanent suture is generally preferred. It is critical to avoid aortic injury while passing the suture through the left crus at the bottom-most suture, which we do by passing the left-handed grasper between the aorta and the left crus before suturing; this creates distance between the aorta and the crus while also deflecting the path away from the aorta. When suturing the right crus, it is similarly critical to avoid injuring the inferior vena cava. Sutures begin posteriorly and are tied sequentially toward the esophagus. We generally include at least one hiatal stitch anterior to the esophagus to help minimize recurrence anteriorly and to avoid abnormally kinking the esophagus with repair of large hiatal hernias where numerous posterior sutures are required. We ensure that the hiatal closure is not overly tight by retracting the esophagus gently in multiple directions and assessing the ease with which an instrument will pass alongside the esophagus through the closure.

Generally, even large defects can be approximated primarily with sutures without excessive tension. If they cannot, relaxing incisions can be performed in the fascial covering of the right or left hemidiaphragm to reduce tension, with that defect closed with mesh. After hiatal closure, a partial fundoplication is generally performed to conclude the procedure. Postoperative care resembles that of other antireflux procedures. However, there is controversy surrounding numerous elements of operative technique, summarized next.

Controversies

Use of Mesh

Paraesophageal hernia recurrence rates exceed 30% in the long run, leading many to propose mesh reinforcement to reduce the recurrence rate. This has not been without controversy. The initial randomized trial by Oelschlager et al. in 2006 showed that biologic mesh reinforcement led to a sizable reduction in short-term recurrence rates, from 24% to 9%, 6 months from surgery. This led many surgeons to favor biologic mesh reinforcement of the hiatal closure, according to the same principles of tension-free closure that are applied in inguinal and ventral hernia repair. However, the 5-year outcomes of Oelschlager's study showed no significant difference in recurrence rates between the two arms (mesh 54%, no mesh 59%, $p = 0.7$). Three subsequent randomized trials have shown no improvement in recurrence rates with mesh use, and Oelschlager's observed improvement in 6-month recurrence rates has not been replicated in these subsequent studies.[202–204] In addition, mesh may cause more long-term side effects, including chest pain and dysphagia.[202,203] Permanent mesh is particularly discouraged because of the possibility of catastrophic complications such as mesh erosion into the esophagus; in current practice, mesh used at the GEJ is typically biologic. Reoperative surgery after prior mesh repairs has a very high complication rate and may require esophagectomy. As such, we currently avoid mesh in paraesophageal hernia repair, with the rare exception of cases with very poor tissue quality or excessive tension despite relaxing incisions. With a relaxing incision, mesh can be used to cover the defect created, without having it right against the hiatal opening or the esophagus. Overall, whether or not to use mesh remains controversial, and practice varies considerably.[200]

Fundoplication

Fundoplication has been traditionally included in paraesophageal hernia repair to prevent the subsequent onset of reflux. Because esophageal manometry is unreliable in this population, and because this population is at risk of esophageal dysmotility because of age and long-standing reflux, a partial fundoplication is typically performed. This limits the risk of postoperative dysphagia relative to a complete (Nissen) fundoplication. A fundoplication is also thought to add bulk to the LES complex with additional suturing that may protect against hiatal hernia recurrence. However, evidence supporting fundoplication is limited. A recent meta-analysis did not identify any RCTs of fundoplication in the setting of paraesophageal hernia repair. In the retrospective studies reviewed, fundoplication was associated with lower risks of recurrent GERD (relative risk [RR] 0.64, $p = 0.07$) and hiatal hernia (RR 0.53, $p = 0.06$), but these findings were not statistically significant.[205] In emergency settings and in patients with severe esophageal dysmotility, omitting fundoplication may be reasonable.

Gastropexy

Some surgeons suture the stomach to the diaphragm to further anchor it in the abdomen. Some surgeons perform gastropexy routinely or preferentially instead of fundoplication. Many surgeons find gastropexy alone preferable in an emergency setting. When a fundoplication has not been performed, gastropexy sutures can be placed between the fundus and the left hemidiaphragm or between the greater or lesser curvature and the anterior abdominal wall. When a fundoplication has been performed, sutures can be placed posteriorly between the fundoplication and the hiatal closure. Gastrostomy tubes may also be placed in an acute setting to anchor the stomach, to provide decompression, or even for eventual feeding. The evidence to date on gastropexy is weak. Current guidelines do not recommend gastropexy in place of fundoplication in the elective setting because it may have inferior reflux outcomes.[206] However, performing gastropexy may be a benign adjunct to fundoplication as long as one does not abnormally kink the GEJ or injure an adjacent structure.[207]

Esophageal Lengthening Procedures

Surgeons generally agree that a 2- to 3-cm segment of intraabdominal esophagus is needed to prevent postoperative GERD and hiatal hernia recurrence. However, there is controversy surrounding the prevalence and management of a "short esophagus" precluding 2 to 3 cm intraabdominal length. Chronic inflammation, dysmotility, and a large hernia can foreshorten the esophagus. This has led some to employ esophageal lengthening procedures such as the Collis gastroplasty, in which linear staplers are used to perform a wedge resection of the fundus that brings the neo-GEJ 3 to 4 cm distally (Fig. 83.24).

Use of esophageal lengthening procedure varies widely by surgeon and center, likely because of practice pattern variation. The true incidence of "short esophagus" is thought to be approximately 10%, of which most cases do not require gastroplasty.[208] We find that in the vast majority of cases, with an adequate mediastinal mobilization, the GEJ will eventually reach into the abdomen off tension. Only 1% to 4% of cases are truly thought to require gastroplasty.[208]

Acute Gastric Volvulus

Acute gastric volvulus, incarceration, and/or obstruction are the feared sequelae of paraesophageal hernias. Gastric volvulus can occur in the organoaxial or mesoaxial plane (Fig. 83.25).

The classic presentation of gastric volvulus is "Borchardt triad": sudden chest or epigastric pain, dry heaving, and inability to pass a nasogastric tube. This is a surgical emergency, as it can progress to gastric ischemia and/or perforation. The first step in management is to pass a nasogastric tube for decompression; this has several benefits: (1) converting an emergent operation into one that can be performed in 24 to 48 hours; (2) facilitating hernia reduction and repair with healthy, decompressed tissue; and (3) allowing resuscitation and correction of electrolyte imbalances before surgery. If a nasogastric tube cannot be passed at bedside, it may be placed endoscopically. If this is unsuccessful, the patient must proceed immediately to surgery. If nasogastric tube placement is successful, the patient may be allowed a brief period of optimization before proceeding with paraesophageal hernia repair during the same hospital admission. Surgical technique during emergency repairs is like that in the elective situation; the stomach must be fully reduced into an intraabdominal position and the hernia must be closed. However, based on the patient's overall fitness and physiology at the time of surgery, some surgeons may defer extensive mediastinal dissection or fundoplication and simply reduce the acute herniation/volvulus and perform suture or double–percutaneous endoscopic gastrostomy (PEG) tube gastropexy instead.

Outcomes

Overall, paraesophageal hernia repair is safe and effective in high-volume centers, with a complication profile like that of other laparoscopic antireflux procedures. Short-term complications that may be more common with large paraesophageal hernias include pleural injury and capnothorax (which are typically inconsequential); injury to the esophagus, stomach, or vagus nerves; and dysphagia. The short-term mortality rate of laparoscopic repair is 0.5%.[201] In the long term, symptom relief is substantial and durable. The radiographic recurrence rate of large paraesophageal hernia repairs is high, approximately 30%, but these are typically small sliding recurrences that do not require reoperation.[201–203,209]

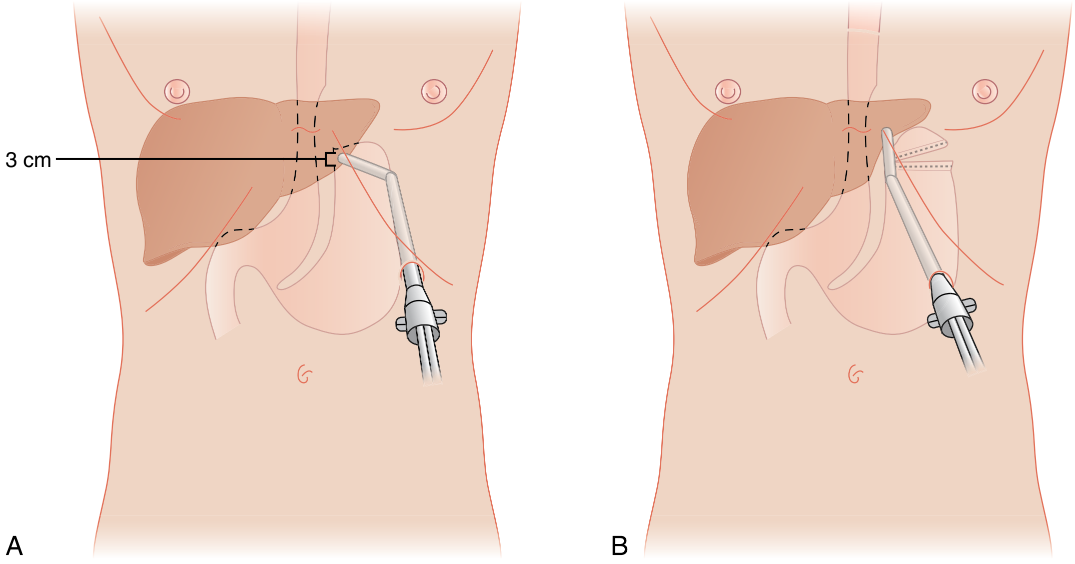

FIGURE 83.24 Technique for laparoscopic Collis gastroplasty. (A) After placing a bougie into the stomach, a linear stapler is used to transect the fundus transversely, approximately 3 to 4 cm distal to the angle of His. (B) A second linear stapler fire is used to resect the fundus parallel to the bougie.

Summary and Conclusion

EPIDEMIOLOGY

Esophageal cancer is the seventh most common cancer in the world, with an incidence of 604,000 new cases in 2020 and accounting for 3.1% of all new cancer diagnoses. In the same year, it was the sixth leading cause of cancer mortality, with 544,000 deaths (5.5% of all cancer-related deaths).[1] In the United States, it is the 17th most common cancer, with 21,560 new diagnoses and 16,120 deaths estimated in 2023.[2] Over the past 40 to 50 years, esophageal cancer survival has markedly improved. From 1973 to 2010, 5-year overall survival (OS) increased from 3.6% to 21.1% for esophageal squamous cell carcinoma (SCC) and from 5.4% to 24.2% for esophageal adenocarcinoma.[3] Despite this, the 5-year OS rate remains only approximately 20%.[2] Because early disease is asymptomatic, most patients are usually diagnosed at an advanced stage when they present with dysphagia. At this point, most will have cancer that has already spread to regional lymph nodes (33%) or to distant sites (38%). Early-stage disease is diagnosed only in 18% of patients (Fig. 84.1).[4]

The global burden of esophageal cancer varies considerably geographically (Fig. 84.2). The highest incidence rates are found in the central Asian "esophageal cancer belt," which spans across the regions of Iran, central Asian republics, and China, followed by Southern and Eastern Africa and Northern Europe.[1] It is a disease of older age, with peak incidence in the sixth and seventh decades.[4] Males are more affected than females, with approximately 70% of cases occurring in males, and there is a twofold to threefold difference in incidence and mortality rates between the sexes.[1]

Esophageal cancer has two predominant histologic subtypes: adenocarcinoma and SCC. They differ in epidemiologic distribution, risk factors, pathogenesis, and clinical and prognostic consequences (Table 84.1). Esophageal SCC is the most common esophageal cancer worldwide, although there has been an overall decline in incidence in the last decade. The majority of cases occur in southern Asia (from China to Mongolia, through India, and to the Middle East). At the same time, there has been an increase in the incidence of esophageal adenocarcinoma, especially in developed countries. Esophageal adenocarcinoma is the more common histology in North America and Western Europe. These trends are thought to reflect changes in the risk factors associated with each histologic subtype, namely, an increasing obesity epidemic and gastroesophageal reflux disease (GERD) contributing to adenocarcinoma, in conjunction with a global decline in alcohol and tobacco abuse, key risk factors for SCC.[1]

RISK FACTORS

The strongest risk factors for esophageal SCC are tobacco and alcohol use, with a synergistic threefold increased risk with both. The relative risk increases with the amount of alcohol consumed and the number of cigarettes smoked. The disease is three to four times more prevalent in males.[1] Dietary factors such as diets low in fruit and vegetables and vitamin and nutrient deficiencies may contribute to SCC. Consumption of foods containing N-nitrosamines, certain pickled vegetables, and high-temperature liquids or foods have also been implicated.[5] Although human papillomavirus (HPV) has been implicated in other SCC cancers, HPV-related SCC represents only a small subset of esophageal SCC, with unclear clinical implications. Disorders of the esophagus that contribute to a chronic inflammatory state, such as achalasia, Plummer-Vinson syndrome, and a history of caustic ingestion, can also increase the risk of SCC. Hereditary cancer syndromes associated with esophageal SCC include tylosis and Fanconi anemia.

As with SCC, esophageal adenocarcinoma has a male predominance. GERD is a major risk factor for esophageal adenocarcinoma. Adenocarcinoma arises in the setting of Barrett metaplasia, an acquired condition from chronic inflammation due to acid exposure. Obesity is another associated risk factor, as is tobacco use.[6] *Helicobacter pylori* infection has been found to be inversely correlated.

	ADENOCARCINOMA	SQUAMOUS CELL CARCINOMA
Epidemiology	Most common in North America and Western Europe	Most common worldwide
Sex predilection	Males	Males
Key risk factors (see Fig. 84.10)	GERD Obesity	Tobacco use Alcohol use
Pathogenesis	Glandular differentiation	Squamous dysplasia
Location in esophagus	80% in distal esophagus or EGJ	Upper third (10%–20%) Middle third (50%) Lower third (40%)

EGJ, Esophagogastric junction; *GERD,* gastroesophageal reflux disease.

PATHOLOGY

A study performed as part of the Cancer Genome Atlas program characterized esophageal cancer and its nearest anatomic neoplastic neighbors, which revealed distinct features differentiating esophageal SCC from adenocarcinoma. SCC bore a stronger resemblance to HPV-negative head-and-neck SCC than to esophageal adenocarcinoma. On the other hand, esophageal adenocarcinoma more closely resembled gastric adenocarcinoma than it did esophageal SCC.[7]

Esophageal SCC arises from the squamous lining of the esophagus in the setting of repeated toxin exposure and chronic inflammation, leading to the development of squamous dysplasia and high-grade intraepithelial neoplasms, the precursor lesion to esophageal SCC (Fig. 84.3).[8] High-grade intraepithelial neoplasia (also described as moderate to severe dysplasia) is carcinoma in situ without violation of the basement membrane. The risk of progression to SCC has been estimated to be 24%, 50%, and 75% at 14 years from diagnosis for low-, moderate-, and high-grade intraepithelial neoplasia, respectively.[9–10] Once tumor cells penetrate the basement membrane, they are considered invasive carcinomas because they invade the mucosa, submucosa, and eventually the muscle layers and adventitia of the esophagus.

Early esophageal SCCs are generally small and appear plaque-like, erosive, or papillary. More advanced lesions can be fungating, ulcerative, or infiltrative. SCC may arise in any part of the esophagus, but most cases occur in the middle third (50%), followed by the lower one-third (40%) and upper one-third (10%–20%). In contrast, the majority (80%) of adenocarcinomas arise in the distal esophagus or at the gastroesophageal junction. These lesions are initially flat or raised patches of mucosa that may become infiltrative, ulcerative, or exophytic at later stages.

Esophageal adenocarcinoma is characterized by glandular differentiation that arises in the setting of Barrett esophagus (BE), a condition defined by the replacement of the normal stratified squamous

epithelium of the distal esophagus by columnar metaplasia due to chronic inflammation secondary to acid exposure. Barrett metaplasia is a precursor to adenocarcinoma, and high-grade dysplasia seen on histopathology is the best predictor for progression to adenocarcinoma. A small subset of esophageal adenocarcinomas exhibit mucinous differentiation and diffuse signet ring cell morphology. There are patients who develop adenocarcinoma without antecedent BE. Carcinoma is thought to result from an accumulation of multiple genetic abnormalities, including inactivating mutations of the tumor suppressor *TP53* gene and subsequent overexpression of oncogenic drivers such as ERBB2 (encoding human epidermal growth factor 2 [HER2]), KRAS, and CCNE1 (see Fig. 84.3).[11,12]

Similar to esophageal adenocarcinoma, the most prevalent genomic aberration in esophageal SCC is *TP53* mutation. Oncogene activation also occurs via amplification of CCND1, MYC, CDK6, EGFR, and genes encoding FGFR ligands (see Fig. 84.3).[13,14]

Both esophageal SCC and adenocarcinoma spread via lymphatics. Lymphatic channels begin in the mucosa and drain into the submucosa of the esophageal wall, forming long collection channels with primarily longitudinal flow. Cervical, supraclavicular, and abdominal lymphadenopathy are seen in both upper and lower esophageal cancers. The incidence of lymphatic spread ranges from 30% to 70%. The deeper the tumor invasion, the higher the likelihood of nodal spread.[15] The two most common sites of distant metastasis are liver and lung; other less common sites are bone, kidney, adrenal glands, and brain.

CLINICAL PRESENTATION

The majority of esophageal cancers are symptomatic at the time of diagnosis. Regardless of histology, dysphagia is the most common symptom. Often, patients will report progressive dysphagia over a period of weeks to months, beginning with an initial episode after eating solid food, after which many patients will adapt by chewing more thoroughly, avoiding hard foods, or drinking liquids with swallows. Eventually, dysphagia with solid food progresses to dysphagia with liquids. Thus, it is only after dysphagia has worsened significantly that patients seek medical attention, by which point the majority have also experienced weight loss. Unfortunately, dysphagia usually signifies locally advanced disease (at least T3). Other associated symptoms may include fatigue, regurgitation, retrosternal pain, dyspnea, and anemia. Locally advanced tumors may also manifest with hoarseness (suggesting laryngeal nerve involvement causing hoarseness) or cough (suggesting tracheoesophageal fistula).

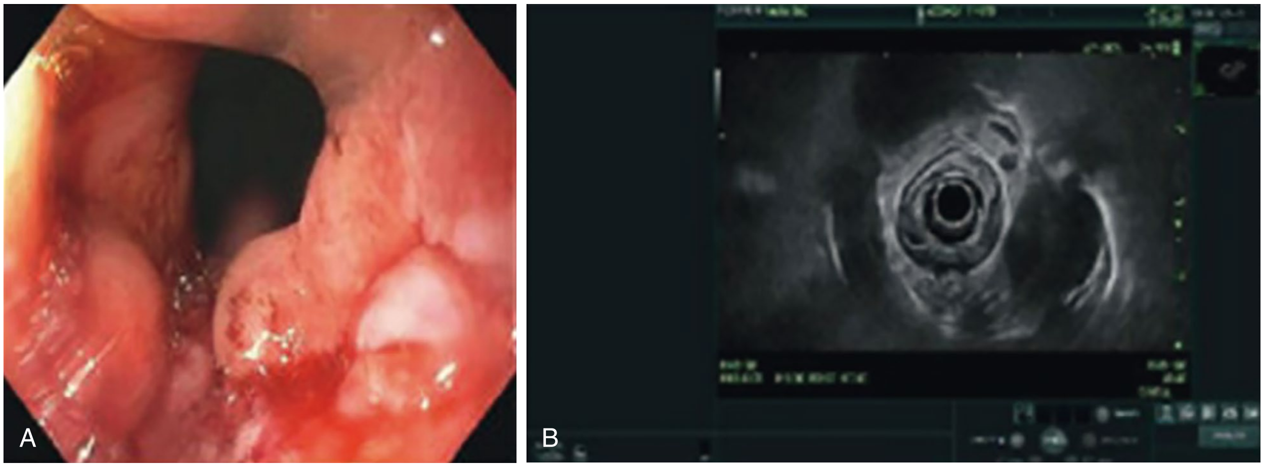
Many, although not all, patients with adenocarcinoma will endorse a long history of reflux symptoms including heartburn and regurgitation. Early-stage tumors, which are usually asymptomatic, are often discovered during endoscopy for BE surveillance. Patients with BE have endoscopic examinations every 3 to 5 years with targeted biopsy samples taken of suspicious lesions and random four-quadrant biopsy sampling. Screening for esophageal squamous dysplasia and SCC is performed in East Asian regions where the incidence is high.[16] Outside of this, there are no defined screening programs.

Physical examination is usually unremarkable and does not generally aid with diagnosis. Weight loss and dehydration can be seen secondary to malnutrition from an obstructed esophageal lumen. However, attention should be paid to supraclavicular and cervical adenopathy. Laboratory evaluation may reveal anemia from chronic blood loss, hypoproteinemia from malnutrition, and hypercalcemia and abnormal liver function tests if there is distant metastatic spread.

DIAGNOSIS AND EVALUATION

The diagnosis of esophageal cancer is made by endoscopy with confirmation by biopsy. Tissue diagnosis is mandatory to determine the histologic subtype and for molecular characterization. If a barium esophagram is obtained, it may demonstrate irregular narrowing, ulceration, or an asymmetric bulge. However, endoscopy should be performed in any patient presenting with dysphagia, even if esophagram suggests a motility disorder.

Esophageal cancers appear as friable, ulcerated masses or as strictures, but the endoscopic appearance can vary (Fig. 84.4A). Early-stage tumors may appear as ulcerations, small nodules, or even flat mucosal irregularities. In many cases, the initial endoscopist may not recognize the presence of cancer, and a single biopsy may not



Partially obstructing esophageal tumor at the GEJ on upper endoscopy

FIGURE 84.4 (A) Endoscopic view of a partially obstructing esophageal tumor at the gastroesophageal junction *(GEJ).* (B) Alternating layers of echogenicity as visualized on endoscopic ultrasound of the esophagus.

be diagnostic. Therefore, multiple biopsies should be performed for any suspicious lesions to attain accurate tissue diagnosis.

During endoscopy, it is essential to note the location of the tumor relative to the incisors and the esophagogastric junction (EGJ), the length of the tumor, and the degree of obstruction. The most proximal extent and circumferential extent of any BE should also be noted according to the Prague criteria.[17] For treatment planning, it is critical to know the upper border for cancers of the cervical and upper thoracic esophagus and the lower border for cancers of the lower thoracic esophagus and EGJ (Fig. 84.5). Adenocarcinomas at the EGJ require particular attention. Under current American Joint Committee on Cancer (AJCC) and National Comprehensive Cancer Network (NCCN) staging guidelines, EGJ adenocarcinomas are staged and classified as esophageal cancers if the tumor's epicenter is no more than 2 cm into the gastric cardia. Tumors with epicenters 2 cm below the EGJ are classified as gastric cancers and treated as such.[18,19]

Once tissue diagnosis is made, accurate clinical staging is essential to guide therapy. Esophageal cancer staging is based on tumor depth (T), nodal involvement (N), and distant metastasis (M). Clinical staging is performed using a combination of complementary modalities: esophagogastroduodenoscopy (EGD) with biopsy, endoscopic ultrasound (EUS), endoscopic ultrasound–fine-needle aspiration (EUS-FNA), endoscopic mucosal resection (EMR) or endoscopic mucosal dissection (ESD), computed tomography (CT), and/or positron emission tomography (PET)/CT.

There are two common strategies for staging that differ based on resources available, scheduling logistics, cost, and patient and physician preference. One strategy involves EGD (with biopsy and possibly endoscopic resection [ER]) and EUS (with or without FNA) to obtain upfront the grade, tumor, and nodal staging. This is followed by fluorodeoxyglucose (FDG)-PET/CT for additional N and M staging. This approach is efficient but costly.[20]

After tissue diagnosis, the second strategy begins with CT or FDG-PET/CT for M staging. No further testing is required if metastatic disease is confirmed. If there is no evidence of distant metastatic disease, then EUS should be done to assess T status and regional lymph nodes. Coupling EUS with FNA of any suspicious nodes further increases the accuracy of this test. Obtaining FDG-PET/CT before EUS has several advantages. FDG-PET/CT may demonstrate distant metastatic disease, eliminating the need for the patient to undergo EUS. FDG-PET/CT may also identify suspicious lymph nodes that can be specifically examined and sampled during the EUS procedure. EUS is superior to CT or PET for assessment of both T and N status.[20] It is highly accurate for celiac nodal status, although slightly lower for other regional lymph nodes because of difficulty accessing the node without traversing the tumor. Obstructing lesions may preclude EUS assessment. In these cases, dilatation to perform EUS is associated with a risk of perforation. Most tumors with such tight stenoses are locally advanced, and patients presenting with dysphagia generally have at least T3 disease. In these situations, practitioners may forego EUS altogether because this represents locally advanced disease for which treatment begins with neoadjuvant therapy regardless.

Although EUS provides information about invasion of adjacent structures, bronchoscopy should also be performed for proximal and middle-third esophageal tumors to assess for direct tracheal invasion. It is important to remember that for more superficial tumors (T1a–T2), the accuracy of EUS is significantly diminished, and EMR provides the most accurate staging information.[19,21]

STAGING AND PROGNOSIS

Staging of esophageal cancer is based on tumor-node-metastasis (TNM) categories (Table 84.2). The 8th edition AJCC staging system acknowledges differences in the biology of adenocarcinoma and SCC by creating separate stage groupings for each histology. Additionally, this is the first edition to separate staging into clinical (cTNM), pathologic (pTNM), and postneoadjuvant pathologic (ypTNM) staging groups. Clinical staging is based on imaging studies (EUS, CT, and PET/CT) (Table 84.3). Pathologic stage is based on microscopic examination of resected specimens (in patients who did not have neoadjuvant therapy) (see Table 84.3). The prognostication based on cTNM differs from that based on pTNM, reflecting the inaccuracies of characterizing tumors by current clinical staging modalities. ypTNM is based on resected specimens in patients who underwent neoadjuvant therapy before surgery (see Table 84.3). This staging was created in response to the increasing number of patients treated in this manner and to account for categories particular to the postneoadjuvant state (i.e., ypT0N0-3M0 and ypTisN0-3M0), dissimilar stage group compositions, and markedly different survival profiles compared with pTNM categories.[20]

Histopathologic cell type affects survival of cTNM-staged patients. SCC features squamous differentiation, whereas adenocarcinoma is characterized by glandular formation. Survival of early- and intermediate-stage patients is worse for SCC than with adenocarcinoma, necessitating separate staging groups for each histology. Additionally, tumor location affects pathologic stage for SCC but not for adenocarcinoma.[20] Tumor location is defined by distance from the incisors to the epicenter of the tumor. For adenocarcinomas located at the EGJ, tumors with epicenters no more than 2 cm into the gastric cardia are staged and treated as esophageal adenocarcinomas, and those extending distally (Siewert III) are staged and treated as gastric cancers.[18]

Tumor grade is included in the pathologic stage classification for early-stage tumors for both adenocarcinoma (pT1-2N0M0) and SCC (pT2N0M) because it is a predictor of survival. However, tumor grade is often inconsistently reported (and not mandated) in biopsy specimens because superficial biopsy samples may not provide enough material to accurately grade cancer differentiation. For both histologies, clinical and postneoadjuvant staging includes only the TNM classification without use of tumor location or grade. Low-grade (G1) and moderately differentiated cancers (G2) are likely subject to interobserver variability. However, poorly differentiated or signet ring cell morphology (G3) is associated with poorer outcome and should be noted.[20]

The depth of invasion of the tumor defines the T status (Fig. 84.6). High-grade dysplasia is defined by malignant cells confined to the epithelium without penetration into the basement membrane and is, by definition, noninvasive (Tis). T1a tumors invade the lamina propria or muscularis mucosa, whereas T1b tumors invade into the submucosa. T2 tumors invade the muscularis propria, and T3 tumors invade the adventitia but not surrounding structures. T4a tumors invade adjacent structures that are usually resectable (diaphragm, pleura, and pericardium). T4b tumors invade adjacent structures that are typically unresectable (trachea and aorta).[18] T3–T4 cancers have a very high (>80%) probability of nodal spread and require neoadjuvant therapy, whereas T1–T2 cancers are likely N0 and can be treated with upfront resection.[22]

T status is most commonly assessed by EUS, which provides a view of the esophageal wall as alternating hyperechoic (white) and hypoechoic (black) layers (Fig. 84.4B). Tumors appear hypoechoic

TABLE 84.2 American Joint Committee on Cancer 8th Edition Cancer Staging Categories for Esophageal and Esophagogastric Junction Cancers

CATEGORY	CRITERIA
Primary Tumor (T)	
TX	Tumor cannot be assessed
T0	No evidence of tumor
Tis	High-grade dysplasia
T1a	Tumor invades the lamina propria or muscularis mucosa
T1b	Tumor invades the submucosa
T2	Tumor invades into but not beyond the muscularis propria
T3	Tumor invades the adventitia
T4a	Tumor invades adjacent structures that are resectable (diaphragm, pleura, azygos vein, peritoneum, or pericardium)
T4b	Tumor invades structures that are usually unresectable (aorta, vertebral body, or trachea)
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in ≥7 regional lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
Histologic Grade (G)	
GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated or undifferentiated
Location (L)—Applicable to Squamous Cell Carcinoma Only	
LX	Location unknown
Upper	Cervical esophagus to lower border of azygos vein
Middle	Lower border of azygos vein to lower border of inferior pulmonary vein
Lower	Lower border of inferior pulmonary vein to stomach, including esophagogastric junction

Modified from Rice TW, Patil DT, Blackstone EH. 8th edition AJCC/UICC staging of cancers of the esophagus and esophagogastric junction: application to clinical practice. *Ann Cardiothorac Surg.* 2017;6(2):1119-1130.

TABLE 84.3 Overview of Staging Schema for Esophageal and Esophagogastric Junction Cancers According to AJCC's 8th Edition

	CLINICAL STAGE (cTNM)	PATHOLOGIC STAGE (pTNM)	POSTNEOADJUVANT PATHOLOGIC STAGE (ypTNM)
Staging based on…	Imaging (EUS, CT, PET/CT)	Microscopic examination of resected specimens (no neoadjuvant therapy)	Microscopic examination of resected specimens (patient received neoadjuvant therapy)
Staging I–V groupings differ for each histology and are based on the listed categories[a]			
Squamous cell carcinoma	T, N, M	T, N, M, grade location	
Adenocarcinoma	T, N, M	T, N, M, grade	T, N, M[b]

[a] For detailed staging tables, refer to Rice TW, Patil DT, Blackstone EH. 8th edition AJCC/UICC staging of cancers of the esophagus and esophagogastric junction: application to clinical practice. *Ann Cardiothorac Surg*. 2017;6(2):1119-1130.

[b] ypTNM stage groupings are the same for both histologies.

(black). The fourth layer on EUS is an important landmark. Hypoechoic cancers are cT1 if there is no invasion of the fourth layer (Fig. 84.6), cT2 if invasion is into the fourth layer, and cT3 if invasion is beyond this layer. If invasion of the fifth layer is detected, the tumor is cT4.[20] EUS, however, is less reliable for cT1 tumors. In this scenario, EMR/ESD is an important adjunct because it is much more effective in confirming EUS cT1 and, furthermore, differentiating cT1a and cT1b.[23–25] In addition to providing more accurate depth of involvement, EMR/ESD can also yield information regarding high-risk features (e.g., lymphovascular invasion) that may weigh heavily in treatment decisions.

Nodal classification (N) is based on the total number of involved regional nodes as assessed clinically by EUS, CT, and FDG/PET. Each examination indirectly assesses the potential for lymph nodes harboring metastases and has its limitations. EUS evaluates size, shape, border, and internal echoic features. CT provides size information primarily. FDG/PET adds metabolic information (Fig. 84.7). These imaging modalities perform similarly and provide moderate levels of accuracy (66% for EUS, 63% for CT, 68% for PET), relatively low sensitivities (42%, 35%, and 35%, respectively), and high specificities (91%, 93%, and 87%, respectively).[26] As such, histologic confirmation via EUS-guided FNA is strongly recommended by the AJCC because it yields the highest sensitivity (92%), specificity (93%), positive predictive value (PPV) (100%), and negative predictive value (NPV) (86%) among the modalities.[27,28]

Contrasted (IV and oral) CT chest and abdomen can be used to detect distant metastasis (M) but has low sensitivity (37%–66%).[29] FDG-PET/CT has comparatively higher sensitivity (69%), specificity (93%), and overall accuracy (84%) and thus increases detection of distant metastasis, albeit with the risk of false-positive findings.[30] Cytologic or histopathologic confirmation of M1 disease is recommended by the AJCC.[18]

Proper staging is critical for treatment decisions. Early-stage tumors (Tis, T1a, and select T1b and T2; no nodal involvement) can be resected alone. Locally advanced tumors (T3 tumors or T2 tumors with nodal involvement) require neoadjuvant therapy and surgery. Stage IV metastatic disease is treated with systemic therapy and/or palliation and best supportive care.

BIOMARKERS

Biomarker testing of biopsy specimens has relevant treatment implications (especially for advanced disease) because the design of new

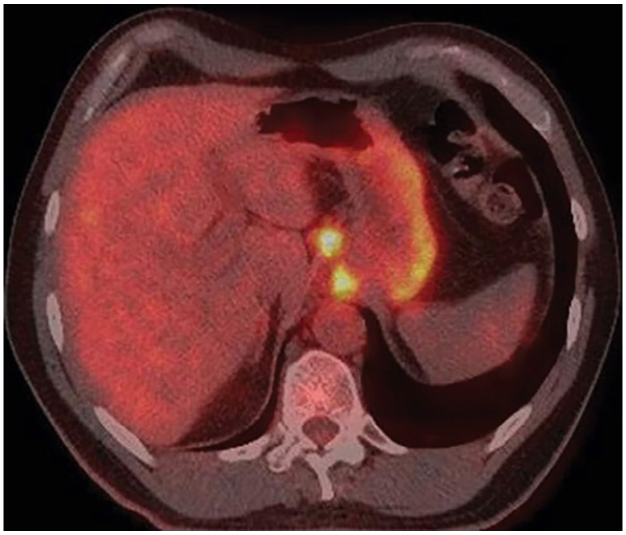

FIGURE 84.7 Fused transaxial PET/CT showing increased fluorodeoxyglucose-avidity of gastroesophageal junction tumor and celiac lymphadenopathy.

therapeutics has focused on the molecular features of esophageal carcinogenesis. Biomarker testing is achieved by immunohistochemistry and/or molecular testing. When tissue is limited, genomic profiling via validated next-generation sequencing (NGS) assays can also be used. Biomarkers of interest include HER2/ERBB2 status, microsatellite instability (MSI) or mismatch repair (MMR) status, programmed cell death ligand 1 (PD-L1) expression, tumor mutational burden-high status, neurotrophic tropomyosin-related kinase *(NTRK)* gene fusions, rearranged during transfection *(RET)* gene fusions, and *BRAF* V600E mutations.

HER2 protein (encoded by the *ERBB2* gene) is the most frequently overexpressed and/or amplified growth receptor in esophageal cancer, more so in adenocarcinoma (15%–30%) than in SCC (5%–13%).[31] Although some studies suggest that HER2 positivity is correlated with tumor invasion, nodal metastasis, and poorer survival, the prognostic significance of HER2 status is still unclear.[32] Nevertheless, HER2 is a target for therapy, specifically with the monoclonal antibody drug trastuzumab.

Expression of the immune checkpoint protein PD-L1 has been correlated with unfavorable survival in esophageal cancer.[33] Approximately 60% of esophageal SCC and 40% of SCC are PD-L1 positive (i.e., have a combined positive score of ≥10).[34] Many immune checkpoint inhibitor (ICI) drugs targeting this pathway are under trial investigation, with some FDA approved. Although MMR deficiency is reported in <1% of esophageal cancers,[7] MSI and MMR status should be evaluated because MMR deficiency is associated with clinical efficacy of ICIs across solid tumors.

An emerging method of interrogating genomic alterations in solid cancers is the liquid biopsy, which evaluates circulating tumor DNA (ctDNA).[35] Liquid biopsy is being used in patients who are unable to have a clinical biopsy for disease surveillance and management. The detection of genetic alterations in DNA shed from esophageal carcinomas can identify targetable alterations or clones with altered treatment response profiles, such as in the case of disease recurrence.

TREATMENT

The management of patients with esophageal cancer requires a multidisciplinary effort that engages the expertise of several disciplines, including surgical oncology, medical oncology, radiation oncology, gastroenterology, radiology, and pathology. Including nutritionists, social workers, case managers, and other supporting disciplines also enhances the care of these patients. The treatment of esophageal cancer has evolved significantly over the past two decades because of greater insight into the biology of the disease, technologic advancements, refinement of surgical technique, improved perioperative care, and novel drug development.

Treatment plans should be individualized for each patient and be based on (1) the stage of their disease; (2) their age, comorbidities, and performance status; and (3) their personal wishes and motivation. Patients presenting with locally advanced disease especially must have the physiologic and functional reserve to undergo a demanding multimodal treatment course that provides the best chance of cure. This requires being able to tolerate rigorous neoadjuvant drug and radiation regimens, recover from major surgery, and potentially meet additional needs for postoperative therapy. The goal is enhancing survival while maintaining quality of life. Factors such as frailty, sarcopenia, malnutrition, and major comorbidities can not only limit the ability of patients to successfully complete treatment but also increase the risk of complications and morbidity.

Overview of Stage-Based Treatment Approaches

Current stage-based treatment algorithms (Table 84.4) are based on a better understanding of the behavior of esophageal cancer. The greater the depth of invasion, the higher the likelihood of lymphatic spread. The strategies employed thus are focused on local control and/or systemic eradication, depending on disease stage.

Historically, esophagectomy was offered for patients with superficial or early-stage disease. However, with the understanding that superficial cancers have a lower risk of nodal involvement and with the evolution of endoscopic technology, ER (endoscopic resection) and ablation are now accepted therapies for high-grade dysplasia (Tis), tumors involving the lamina propria or muscularis propria (T1a), and select superficial adenocarcinomas involving the submucosa (T1b).[19] Importantly, the success of endoscopic therapy is contingent on meticulous pathologic review and patient commitment to surveillance endoscopies.

Although T1b lesions that involve the most superficial third of the submucosa (SM1) have relatively low rates of nodal metastases (possibly <10%), T1b lesions in the deeper two-thirds of the submucosa (SM2/SM3) may have nodal involvement in almost 40% of cases.[36] T1b cancers of SCC histology also appear to have a higher risk of nodal metastasis compared with adenocarcinoma (45% vs. 26%).[37] Therefore, esophagectomy is recommended for T1b esophageal adenocarcinoma with high-risk features and for T1b esophageal SCC.

Management for T2 lesions remains controversial because of unreliable clinical staging modalities. Many of these patients are under- or overstaged and therefore are at risk for over- or undertreatment, respectively. EUS has been reported to be unreliable in staging cT2 cancers, yielding only 13% accuracy.[38,39] A review of the Society of Thoracic Surgery database found that of 482 clinically staged T2N0 patients treated with upfront surgery, only 27% were confirmed as pathologic T2N0, whereas 26% were downstaged and 47% were upstaged. The majority of patients were upstaged due to the finding of occult nodal disease on pathologic review.[40] Given the high incidence of occult nodal disease and the unreliability of clinical staging for T2 tumors, some clinicians believe that these patients stand to benefit from multimodal treatment (neoadjuvant therapy with surgery) rather than surgery alone. However, routine use of this approach may result in overtreatment with its associated morbidity and costs. As such, treatment decisions for these patients should factor in low- and high-risk pathologic features. The NCCN guidelines recommend that clinical T1b–T2, low-risk lesions <3 cm in diameter and well-differentiated can be surgically resected up front. Higher-risk lesions (poorly differentiation, ≥3 cm, positive lymphovascular invasion) should undergo multimodal therapy.

Approximately 32% of patients are found to have locoregional disease at diagnosis. Dysphagia generally signifies T3 disease with approximately 80% probability of lymph node metastasis. Therefore, patients with T3-4aN0 or any clinical nodal disease (cT1b–4aN+)

TABLE 84.4 Stage-Based Treatment Approaches and Strategies for Esophageal Cancer by Histologic Subtype

	STAGE	ADENOCARCINOMA	SQUAMOUS CELL CARCINOMA
Early-stage disease	pTis pT1a cT1bN0–cT2N0 low risk (well differentiated, no lymphovascular invasion, <3 cm)	ER ± ablation *or* Esophagectomy	ER ± ablation *or* Esophagectomy
	cT1bN0–cT2N0 high risk (moderate to poorly differentiated, lymphovascular invasion, invasion depth beyond superficial one-third or >500 um into submucosa)	Esophagectomy	Esophagectomy (noncervical esophagus)
Locally advanced, resectable disease	cT2N0 cT1b–T2, N+ cT3–T4a, N+	Neoadjuvant chemoRT + esophagectomy *or* Perioperative chemotherapy + esophagectomy *or* Definitive chemoradiation	Neoadjuvant chemoRT + esophagectomy *or* Definitive chemoradiation (cervical esophagus)
Locally advanced, unresectable disease	cT4b, N+	Definitive chemoradiation *or* Systemic therapy *and/or* Palliation/best supportive care	Definitive chemoradiation *or* Systemic therapy *and/or* Palliation/best supportive care

chemoRT, Chemoradiation; *ER,* endoscopic resection.

and who are medically fit require multimodal therapy (i.e., neoadjuvant therapy followed by esophagectomy). This approach has been shown in multiple large, randomized controlled trials to confer the best survival outcomes for this patient population.

Tumors that have invaded into the adjacent structures, such as the aorta, vertebral body, or trachea (T4b), are considered unresectable, for which definitive chemoradiation is recommended. Definitive chemoradiation is also an option for those who decline surgery or are not fit for surgery. Patients with stage IVA (T4b or unresectable N3) and stage IVB (metastatic disease) may be treated with systemic therapy and/or palliation and best supportive care.

Treatment Modalities

Treatment modalities employed for esophageal cancer include surgery, chemotherapy, radiation, and endoscopic therapy. Targeted therapies and immunotherapy are emerging strategies. Each modality plays a different role in eliminating cancer cells, and in most cases, they must be used in combination (multimodality therapy) to achieve the best oncologic outcome, especially for locoregional disease. The rationale for endoscopic therapy, surgery, and radiation is to control local disease, whereas chemotherapy, targeted therapy, and immunotherapy address disease at a systemic level.

Endoscopic Therapies

Because BE is a known precursor lesion to esophageal adenocarcinoma, a surgeon should be familiar with its management. BE is the result of metaplastic changes in the distal esophagus associated with chronic GERD whereby normal squamous epithelium is replaced by columnar epithelium with goblet cells (i.e., intestinal metaplasia). Therefore, diagnosis is made histologically on biopsies obtained above the Z line. Grossly, BE appears as salmon pink–colored extensions (“tongues”) of mucosa from above the EGJ into the esophagus. Assessment of BE requires a high-quality endoscopic examination. Disease burden is quantified by the Prague C&M criteria, which characterize the circumferential (“C”) and longitudinal (“M”) extent of BE based on standardized landmarks.[40–42] For screening and surveillance, BE should be sampled according to the Seattle protocol, which dictates obtaining four-quadrant biopsies every 2 cm through the length of BE or every 1 cm in patients with a history of BE and dysplasia, in addition to targeted biopsies of all visible lesions (i.e., depressed, flat, raised mucosal abnormalities).[43]

Presence of dysplasia within BE requires confirmation by a second pathologist. The degree of dysplasia within BE is the best current marker to predict progression to esophageal adenocarcinoma and therefore determines management by continued surveillance or endoscopic eradication therapy (EET) (Fig. 84.8).[17] Surveillance involves endoscopy with biopsy at defined time intervals. EET offers an effective and minimally invasive alternative to esophagectomy and involves ER of any visible lesion within the BE segment followed by ablative techniques (e.g., radiofrequency ablation [RFA] and cryotherapy) to achieve complete eradication of dysplasia and intestinal metaplasia.

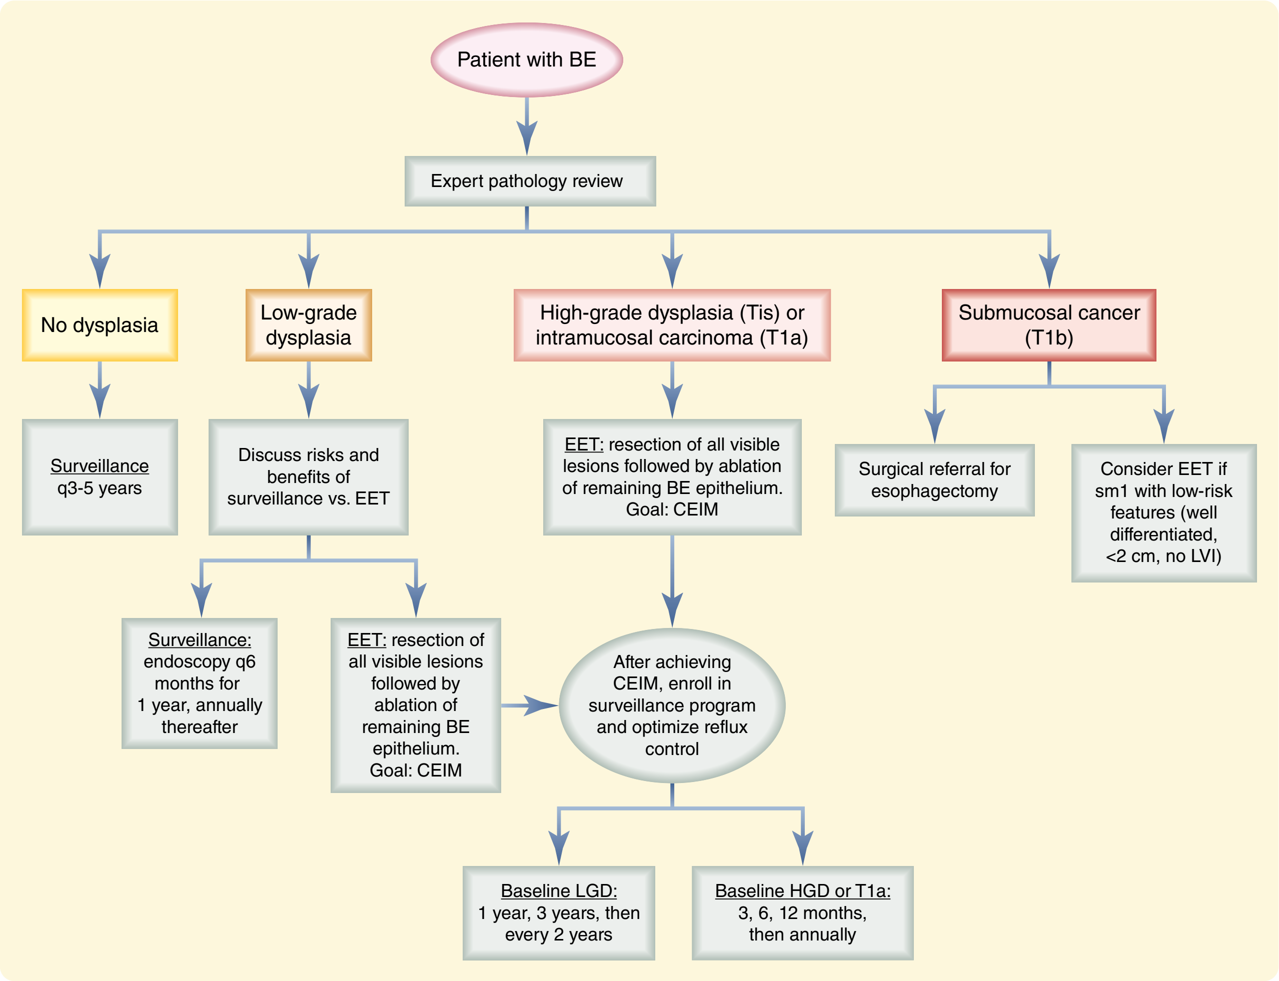
BE without dysplasia has a very low risk of progression to cancer, and therefore, surveillance is recommended. After the initial diagnosis, a repeat EGD with biopsy should be done within 1 year because of the relatively high incidence of missed cancer or inadequate sampling on initial endoscopy. If there are no findings of dysplasia, then EGD with biopsy can be repeated every 3 (for >3-cm BE segment) to 5 years (if <3-cm BE segment). For patients with *BE with low-grade dysplasia,* either endoscopic surveillance or EET is appropriate based on a risk-benefit discussion. Management of BE with low-grade dysplasia is challenging because of high interobserver variability among pathologists, the variable natural history of the disease (including regression in some cases), and lack of well-defined risk stratification tools. EET is suggested, but if a patient should prefer to avoid the risks related to EET, surveillance is appropriate. Surveillance is recommended every 6 months for 1 year, followed by annual endoscopy (unless the degree of dysplasia changes). In the case of *BE with high-grade dysplasia* (or T1a intramucosal carcinoma), endoscopic eradication is strongly recommended over surveillance or surgical resection. After eradication therapy, patients must continue an endoscopic surveillance program.[17] Complete eradication of intestinal metaplasia is standardly considered as two endoscopic examinations at least 3 months apart during which no visible or histologic evidence of BE is found on biopsy.[44]

In terms of the role of chemoprevention and antireflux procedures to reduce the risk of neoplastic progression in BE, at least daily proton pump inhibitor (PPI) therapy is recommended to control associated GERD symptoms. Twice-daily dosing should be used during eradication to favor growth of normal squamous epithelium. Antireflux surgery is very effective at reducing reflux episodes, decreasing symptoms, and healing esophagitis. Although trials have shown equivalent effect as medical therapy to control GERD,[45] surgery should be considered for patients who have poor symptom control with medications, large hiatal hernias, or difficulty with BE eradication. Although there is some evidence that fundoplication may delay development of dysplasia in BE, the data do not convincingly show that patients with BE treated with antireflux surgery have a lower risk of progression to neoplasia than those treated with medical therapy. Moreover, the risk of progression to cancer in the setting of nondysplastic BE is so low that surgery and its inherent risks may not be merited in patients who otherwise do not need fundoplication for symptoms already controlled by medication. In other words, the guidelines currently suggest against the use of antireflux surgery as an antineoplastic strategy in BE.[17] However, antireflux surgery should be pursued for patients with symptoms or complications of GERD that fail medical management or for those noncompliant with or unable to take PPIs due to side effects.

Various endoscopic ablative (cryotherapy, RFA, photodynamic therapy) and resection (endoscopic mucosal resection [EMR], endoscopic submucosal dissection [ESD]) techniques have largely supplanted the role of esophagectomy for high-grade dysplasia and superficial esophageal cancers. High-grade dysplasia (pTis) and early-stage disease (pT1a, select small pT1b adenocarcinoma with low-risk features) can be effectively treated with ER and/or ablation. The goal of endoscopic therapy is complete removal of early-stage lesions and complete eradication of Barrett’s mucosa.

Ablative therapy uses energy to generate extremes of heat to destroy tissue. RFA transmits radiofrequency energy via balloon or electrical plate to generate heat (Fig. 84.9). Cryotherapy uses cold liquid nitrogen to deliver extreme cold. Photodynamic therapy involves systemic administration of a photosensitizing drug with an affinity for tumors. A laser light directed at the lesion triggers a destructive photodynamic reaction. Multiple studies have shown the effectiveness of RFA and cryotherapy in eradicating BE and dysplasia. These ablative techniques also offer alternative treatment options when lesions are challenging to resect or as salvage therapy after prior failed RFA.

There are two important limitations of ablative therapies: limited depth of penetration and the lack of definitive pathologic analysis. Areas of BE with nodular or ulcerated features or with



Patient with BE
Expert pathology review
No dysplasia
Low-grade dysplasia

other abnormalities concerning for superficial invasive cancer should undergo ER rather than ablation to yield tissue for pathologic analysis of depth of invasion. EMR and ESD remove the full thickness of mucosa down into the submucosa. The basic technique of EMR is incising lesions by a through-the-scope snare with or without cautery. For flat lesions, adjunctive techniques, such as double-channel endoscope, submucosal injection, and cap- and ligation-assisted EMR, are needed. EMR can remove lesions <2 cm in size en bloc. Larger lesions require removal in piecemeal fashion, which may limit margin assessment. On the other hand, ESD allows en bloc dissection of a lesion regardless of size. It is performed by injection of fluid into the submucosa, creating an incision around the perimeter of the lesion, and carefully dissecting the lesion from the deeper layers using a specialized knife. It is labor intensive and has a greater risk of perforation but is favored over EMR for lesions larger than 15 mm, lesions with poor lifting (due to fibrosis), and better assessment of depth of invasion if there is concern for submucosal invasion. In Japan and Europe, there are guidelines that provide specific recommendations on the use of ESD, but no guidelines currently exist in the United States.[46,47]

The NCCN guidelines recommend EMR with or without ablation in patients with Tis and T1a tumors as well as superficial T1b adenocarcinomas with low-risk features (well or moderately differentiated, no lymphovascular invasion, mucosal penetration <500 micrometers) as preferred therapy over esophagectomy. EMR successfully eradicates 91% to 98% of T1a cancer.[47] A large retrospective analysis of the Surveillance, Epidemiology, and End Results (SEER) database that reviewed patients who underwent surgery versus endoscopic therapy for T1N0 esophageal cancer found that patients treated with endoscopic therapy had better cancer-specific survival and equivalent OS.[48] EMR is considered a relatively safe technique, with complications including bleeding (10%), perforation (3%), and stricture formation.[46,47]

Surgery

Esophagectomy is a key component of curative treatment for esophageal cancer. The first successful esophagectomy for cancer was performed by Franz Torek in 1913. Since that time, vast improvements in surgical techniques and perioperative care have contributed to a marked reduction in surgical morbidity and mortality. Esophagectomy should be offered for all patients with resectable esophageal cancer (>5 cm from the cricopharyngeus) who are medically fit. Enteral nutritional support should be considered for patients with significant dysphagia and/or weight loss before or during neoadjuvant therapy, with preference for jejunostomy feeding tube over gastrostomy tube to preserve the stomach as a conduit for reconstruction.

The NCCN guidelines emphasize that esophagectomies should be done at high-volume centers based on studies that showed a correlation between hospital volume and surgical mortality. In 2002, a study in the *New England Journal of Medicine* showed that mortality ranged from the single digits at high-volume centers to above 20% at low-volume centers.[49] A follow-up study in 2011 found that just over 30% of esophagectomies had moved to high-volume centers, with an associated 11% decrease in surgical mortality.[50]

Several approaches for esophageal resection exist and can be done open or with minimally invasive techniques. The types of esophagectomies include Ivor Lewis, McKeown (“three-hole”), transhiatal, and left transthoracic/thoracoabdominal—they differ in the types of incision and the location of the anastomosis (cervical or thoracic). The choice of operative approach depends on the tumor location and surgeon preference.

Minimally invasive esophagectomy (MIE) can be performed using video-assisted laparoscopy and thoracoscopy as well as robot-assisted approaches. These procedures are associated with a steep learning curve and higher technical complexity than open approaches.[51] Some surgeons use a hybrid open/minimally invasive approach as well. Nevertheless, MIE is becoming increasingly embraced by surgeons around the world. In the United States, use of MIE increased from 38% in 2010 to 57% in 2015.[52] Randomized trials comparing different MIE approaches to open esophagectomy suggest that MIE is associated with a lower incidence of pulmonary and major complications, shorter length of hospital stay, and faster functional recovery.[53,54] Furthermore, MIE is associated with similar survival outcomes to those observed with open surgery. A trial comparing robot-assisted MIE to non–robot-assisted MIE is ongoing.

Regardless of the type of resection or selected approach, the goal of surgery for curative intent is achieving complete resection with negative microscopic margins (R0) and adequate lymphadenectomy (of thoracic and abdominal fields) (Fig. 84.10). The extent of lymphadenectomy has significant prognostic implications; data from several large registry studies and multi-institutional retrospective studies indicate that extended nodal dissection might have survival benefit beyond the purpose of pathologic disease staging. The number of lymph nodes removed has been shown to be an independent predictor of survival. Although the total number of lymph nodes needed to ensure accurate staging and prognostication is not actually known, the evidence continues to suggest that more is better. Currently, the NCCN guidelines recommend thorough dissection to achieve at least 15 lymph nodes for pathologic examination in patients undergoing resection with and without preoperative therapy.[19]

After the resection phase of the operation, reconstruction to create a neoesophagus involves preparation of a well-perfused conduit and creating a tension-free esophagogastric end-to-side or side-to-side anastomosis either stapled or hand-sewn. A gastric conduit relying on blood supply from a preserved right gastroepiploic artery is preferred for esophageal reconstruction. In some centers, select patients at high risk for conduit ischemia undergo preoperative selective embolization of the right gastric, left gastric, and splenic arteries as a strategy for gastric conditioning to minimize the risk of anastomotic leak or conduit failure. If the stomach cannot be used, such as in patients who have had previous surgery or other procedures that may have devascularized the stomach, the colon or the jejunum are alternative conduit options.

A cervical anastomosis allows more extensive resection of the esophagus, possibly avoiding thoracic access and less severe reflux symptoms. An anastomotic leak in the neck is easier to control than one in the chest. However, advantages of a thoracic anastomosis may include lower incidence of anastomotic leak (presumably due to less tension), lower stricture rate, and lower rate of left recurrent nerve injury.[55] In a prospective randomized trial, cervical and thoracic anastomoses after esophageal resection were equally safe and had similar oncologic outcomes when performed in standardized fashion.[56] In the era of minimally invasive surgery, a randomized clinical trial showed much lower leak rates with intrathoracic (12.3%) than with cervical anastomosis (31.7%) in patients undergoing transthoracic MIE for mid- to distal and EGJ tumors.[57]

Whether done with an open or minimally invasive approach, the transthoracic Ivor Lewis esophagectomy involves intrabdominal and intrathoracic exposure and is the most commonly performed esophageal resection worldwide (see Fig. 84.10). It allows visualization of the entire intrathoracic esophagus and complete intrathoracic

(Adapted from Yassin E, van Workum, van den Wildenberg F, et al. European consensus on essential steps of minimally invasive Ivor Lewis and McKeown esophagectomy through Delphi methodology. *Surgical Endoscopy.* 2022;36[1]:446-460.)

lymphadenectomy. The operation begins with the abdominal portion (by laparotomy or laparoscopy), in which the stomach is mobilized with dissection of the celiac and left gastric lymph nodes, division of the left gastric artery, and preservation of the right gastroepiploic as the main blood supply for the gastric conduit. After tubularization of the stomach to be used as the conduit, the patient is repositioned for right chest access via thoracotomy or thoracoscopy. The thoracic portion involves circumferential mobilization of the esophagus, resection of the tumor (with the esophagus) to negative margins, and pulling the gastric conduit up into the chest for creation of the esophagogastric anastomosis at or above the azygos vein. The Ivor Lewis approach may be used for distal esophageal lesions but is inadequate to obtain an acceptable margin for lesions in the midesophagus.

In cases of more proximal tumors or when there is concern for attaining an adequate proximal margin, the McKeown (three-hole) esophagectomy is preferred (see Fig. 84.10). The McKeown esophagectomy is applicable for tumors in any part of the esophagus and situates the anastomosis in the neck. Similar to the Ivor Lewis esophagectomy, it also takes a transthoracic approach and is performed in a similar fashion, except that the thoracic portion is performed first, followed by the abdominal portion and finishing with the cervical portion. The esophagus is exposed via a left neck incision, with careful attention to avoid recurrent laryngeal nerve injury. The conduit is pulled up through the chest to create an esophagogastric anastomosis in the neck.

The transhiatal esophagectomy avoids opening the chest and is accomplished via abdominal and cervical incisions. The abdominal portion is done in a similar fashion to the Ivor Lewis esophagectomy. Mobilization of the thoracic esophagus and mediastinal dissection is done via the hiatus in “blinded” fashion, although visualization is improved if done laparoscopically. The gastric conduit is pulled up through the posterior mediastinum and exteriorized in the cervical incision for the anastomosis. This approach may be used for lesions at any location. Because it avoids opening the thoracic cavity, it is the least invasive of the approaches, requires less operative time, and yields lower pulmonary complications and morbidity.[58] With regard to oncologic outcome, a randomized clinical trial showed that although median overall, disease-free, and quality-adjusted survival did not differ statistically between transhiatal esophagectomy and transthoracic esophagectomy with extended en bloc lymphadenectomy, there was a trend toward improved long-term survival at 5 years with the latter approach. Still, many experts believe that the transhiatal approach is oncologically inadequate (by virtue of subpar nodal dissection), and transhiatal dissection of large, midesophageal tumors adjacent to the trachea may be challenging and hazardous. As such, transhiatal esophagectomy may then be more suitable for early-stage tumors.

Less common approaches are the left transthoracic or thoracoabdominal esophagectomy, which uses a contiguous abdominal and left thoracic incision through the eighth intercostal space. This approach may be useful for bulky lesions in the distal esophagus or for patients in which the right chest cannot be accessed. The anastomosis is placed in the left chest.

Esophagectomy is a complex procedure and is associated with major morbidity in 30% to 40% of patients. However, 30-day and in-hospital mortality have steadily declined from 8% to 10% in the 1990s down to 2% to 4% currently.[59,60] Common postoperative complications after esophagectomy are atrial fibrillation, respiratory compromise, anastomotic/conduit complications, and chyle leak. As with other thoracic procedures, atrial fibrillation is most common, especially in older patients. Postesophagectomy patients are also at high risk for respiratory complications, such as aspiration and pneumonia. Early ambulation and aggressive pulmonary toilet are thus critical in postoperative care. Anastomotic leak is a highly morbid complication. CT with oral contrast or endoscopy can confirm the diagnosis. Management depends on the location of the anastomosis, the patient's clinical stability, and the severity of the dehiscence. Cervical anastomoses can be managed with a bedside neck washout and negative-pressure therapy. If small, a thoracic anastomosis can be covered with a stent. A larger anastomotic breakdown may require reoperation. Endovac therapy is now also a viable option to manage these leaks. Anastomotic stricture is a late complication presenting with dysphagia and can be treated with endoscopic balloon dilatation.

To address perioperative morbidity, centers have implemented enhanced recovery or fast-track programs with results suggesting fewer intensive care unit (ICU) days, shorter length of stay, reduced costs, and fewer complications. There is now also growing interesting in implementation of "prehabilitation" programs for patients before surgery focused on preoperative exercise and nutrition regimens. Multiple ongoing studies are examining the impact of such programs on in-hospital complications as well as on postoperative morbidity and quality of life. Prospective studies have shown that most postesophagectomy patients return to baseline quality-of-life status at about 1 to 3 years.[61]

Radiation

Radiation was historically the first treatment modality for esophageal cancer. The method of delivery and particles used have evolved significantly. With improved surgical care, radiotherapy was then incorporated into multimodal treatment to gain additional local control within or around the operative field in an attempt to reduce local recurrence. It is now part of standard treatment for locally advanced esophageal cancer and used concurrently with chemotherapy in the preoperative setting for resectable disease and as definitive or palliative therapy for those with unresectable disease.

Modern advances in radiotherapy are related to overall reduction of irradiation volume as compared with historical standards and development of techniques to deliver a radiation dose that is conformational to the target. Technologies such as intensity-modulated radiotherapy (IMRT) and proton-beam therapy (PBT) substantially reduce irradiation of nontarget tissues, thereby resulting in fewer side effects, and are associated with fewer postoperative complications.[62]

For patients being treated with definitive chemoradiation, investigative efforts have focused on determining the optimal dose to address high rates of locoregional failure. So far, large trials (INT-0123 and ARTDECO) have not shown better locoregional disease control with higher radiation doses.[63,64] Accordingly, the current standard of care dictates delivery of at least 50 Gy for definitive chemoradiation. For neoadjuvant treatment, 41.4- to 50.4-Gy radiotherapy combined with chemotherapy is recommended. In the palliative setting, conventional modest dose (30–35 Gy) is effective for mitigating malignant dysphagia.[19]

Chemotherapy

Because esophageal cancer has likely spread systemically in most patients at time of diagnosis, chemotherapy plays an important role in treating both resectable locally advanced and unresectable disease. Chemotherapeutic drugs exert cytotoxic effects on tumor cells. Administered systemically, chemotherapy is intended to treat the primary tumor itself and disease that has spread beyond the primary site. Even in the setting of seemingly localized disease, chemotherapy has the potential to target clinically undetectable micrometastatic deposits. It can downstage marginally resectable tumors, improve the chance for R0 resection, and decrease the incidence of locoregional recurrence. It can also have a synergistic antitumor effect when used with radiation. Furthermore, when administered preoperatively, the biologic response can be evaluated and quantified pathologically in terms of tumor viability and inform prognosis. The challenge with chemotherapy has been determining the most synergistic combinations at doses to maximize antitumor effect while minimizing toxicity and side-effect profiles.

Early prospective randomized trials found an effective role for preoperative chemotherapy for both locally advanced adenocarcinoma and SCC. In 2002, the England Medical Research Council (MRC) trial studied 802 patients treated with neoadjuvant cisplatin/5-fluorouracil and surgery versus surgery alone. The results showed that neoadjuvant chemotherapy significantly enhanced the R0 resection rate (60% vs. 54%), increased the median survival time (16.8 months vs. 13.3 months), and prolonged the 2-year survival rate (43% vs. 34%) compared with surgery alone.[65] Subsequently, in 2009, a long-term update of the MRC trial (known as the UK OEO2 trial) was the first to show a significant OS benefit with neoadjuvant chemotherapy. Patients who had received neoadjuvant chemotherapy and surgery had a 5-year survival of 23.0% versus 17.1% in patients who had surgery alone.[66] In both studies, the survival benefit was observed for both adenocarcinoma and SCC. These initial studies launched a number of landmark randomized trials that helped establish preoperative and perioperative chemotherapy as standard of care (and will be discussed in the "Multimodal Therapy for Locally Advanced Disease" section).

Before 2000, the only FDA-approved drugs used for esophageal cancer included the platinums (cisplatin, carboplatin), anthracyclines (epirubicin, doxorubicin), and pyrimidine analogues (5-fluorouracil [5-FU]). In the early 2000s, oxaliplatin (a third-generation platinum) and capecitabine (a newer version of 5-FU) came into use, with similar efficacy and toxicity profiles. Later in that decade, taxanes (docetaxel, paclitaxel) were FDA approved for use in upper GI cancers.

Targeted Therapy

The role of targeted therapies is primarily in advanced metastatic disease, and they are used in combination with chemotherapy.

HER2 is an important biomarker and key driver of tumorigenesis in esophageal cancer. Based on the success of trastuzumab (an anti-HER2 monoclonal antibody) in breast cancer, the drug was also studied for gastric and EGJ adenocarcinomas. Although the majority (80%) of patients in the ToGA trial had gastric cancer, the results showed increased median OS with the addition of trastuzumab compared with chemotherapy alone (13.8 months vs. 11 months).[67] Trastuzumab deruxtecan (an antibody-drug conjugate) is now the standard second-line treatment option for patients with HER2-positive gastroesophageal adenocarcinoma after showing improvement in OS over chemotherapy alone (median 12.5 months vs. 8.4 months).[68] Another FDA-approved second-line therapy is ramucirumab, a monoclonal antibody targeting vascular endothelial growth receptor (VEGFR). The REGARD trial showed a survival benefit with this drug for patients who failed first-line chemotherapy for EGJ adenocarcinoma.[69]

Additionally, the FDA approved the use of select tropomyosin receptor kinase (TRK) inhibitors for *NTRK* gene fusion–positive tumors, selpercatinib for *RET* gene fusion–positive tumors, and dabrafenib/trametinib for tumors with *BRAF* V600E mutations.

Immunotherapy

Immunotherapy has emerged as a significant strategy across all fields of oncology. Specifically, therapies known as *immune checkpoint inhibitors* (ICIs) target pathways that allow cancers to evade immune attack. Binding of PD-L1 on the surface of cancer cells to the programmed cell death 1 (PD-1) on T and B lymphocytes activates a pathway that prevents T cells from recognizing cancer as foreign. ICIs are monoclonal antibodies that bind either to PD-L1 (atezolizumab, durvalumab) or PD-1 (nivolumab, pembrolizumab) and block this pathway, thereby facilitating T-cell–mediated antitumor response. Another set of ICIs targets the cytotoxic T-lymphocyte–associated protein 4 (CTLA-4) pathway (ipilimumab, tremelimumab). Treatment with ICIs is based on testing for MSI or MMR, PD-L1 expression, or high tumor mutational burden (TMB).

The effectiveness of ICIs has been demonstrated in many cancers, including malignant melanoma and non–small cell lung cancer. Numerous phase III trials have evaluated ICIs in patients with esophageal cancer, leading to FDA approvals across multiple lines of therapy. One key observation from these trials is that ICIs have greater efficacy against SCC than against adenocarcinoma. Furthermore, tumors with higher PD-L1 positivity (combined positive score [CPS] or tumor area positive ≥ 10) were associated with improved efficacy.[70] Thus far, anti–PD-1 drugs (nivolumab, pembrolizumab) are indicated in combination with chemotherapy or with ipilimumab in the first-line treatment of advanced-stage esophageal SCC and as monotherapy in the second-line setting. The benefit of ICIs for esophageal adenocarcinoma remains unclear.

The role of immunotherapy in multimodal treatment for locally advanced disease was most recently demonstrated in the phase III CheckMate 577 trial. Patients with locally advanced esophageal cancer (SCC and adenocarcinoma) treated with neoadjuvant chemoradiation with residual pathologic disease after resection were randomized to either adjuvant nivolumab or placebo. Patients in the nivolumab arm experienced a median disease-free survival (DFS) of 22.4 months as compared with 11.0 months with placebo. Adjuvant nivolumab also had longer metastasis-free survival. As such, nivolumab is FDA approved for patients with completely resected esophageal or EGJ tumors with residual pathologic disease who had received neoadjuvant chemoradiation.[71]

Studies are underway to investigate the role of immunotherapy in the neoadjuvant setting, such the as MATTERHORN trial (durvalumab with fluorouracil, leucovorin, oxaliplatin, and docetaxel [FLOT]).[72] As the results of ongoing trials are reported, immunotherapy may change the landscape of multimodal treatment in the near future.

Multimodal Therapy for Locally Advanced Disease

Each treatment modality offers a different mechanism for eliminating cancer, but no treatment alone is sufficient for locoregional disease. Although surgical resection was the mainstay of esophageal cancer treatment in the past, it became clear that even the most radical resections with extensive lymph node dissection are not enough to cure locoregionally advanced disease. Distant recurrence or metastatic disease continues to be the primary cause of mortality. Therefore, adding other modalities of treatment to surgery is necessary.

Large randomized controlled trials investigating combining these modalities and the sequence of each have led to considerable progress in treating resectable locally advanced esophageal cancer, overall demonstrating that neoadjuvant therapy with surgery significantly increases survival compared with surgery alone. (*Neoadjuvant therapy* refers to all treatment before surgical resection, whereas treatment occurring after surgery is termed *adjuvant therapy*. The term *induction therapy* is sometimes used interchangeably with *neoadjuvant therapy*. However, *induction* specifically refers to delivery of chemotherapy before radiation therapy [RT], in contrast with concurrent chemoradiotherapy.)

For resectable locally advanced esophageal cancer, neoadjuvant therapy followed by surgery has become the standard of care. Neoadjuvant therapy aims to downsize tumors, increase local control, improve rates of R0 resection, and eradicate undetected metastatic disease. Two main strategies are supported: (1) neoadjuvant chemoradiation and (2) perioperative chemotherapy. Regimens within these schemes are variable. Therefore, treatment plans should be made in multidisciplinary fashion and tailored to each patient's specific disease and traits. Restaging FDG-PET/CT should be done at 5 to 8 weeks after completion of neoadjuvant therapy before proceeding with surgery.

A third option, definitive chemoradiation, exists for patients with resectable disease but deemed not medically fit to undergo surgery or who decline surgery. Definitive chemoradiation is also indicated for patients with unresectable (T4b) locally advanced disease.

Neoadjuvant Chemoradiation

For the treatment of locally advanced esophageal cancer, preoperative chemoradiation is associated with improved OS, DFS, and pathologic complete response (pCR) as compared with surgery alone (Table 84.5).[73–75]

The landmark multicenter phase III randomized Chemoradiotherapy for Oesophageal Cancer Followed by Surgery (CROSS) trial (2012) showed that preoperative chemoradiation significantly improved OS and DFS compared with surgery alone in patients with resectable locally advanced (T2–T3, N0–N1, M0) esophageal and EGJ cancer. The majority (75%) of patients had adenocarcinoma, and 23% had SCC. The chemoradiation regimen consisted of carboplatin and paclitaxel administered concurrently with RT (41.4 Gy in 23 fractions). Esophagectomy was performed within 4 to 6 weeks in the treatment group and immediately after randomization in the control group. A number of significant observations were made. In the preoperative chemoradiation arm, the rate of R0 resection was higher than in the surgery-alone group (92% vs. 69%). In patients with SCC, those who received preoperative chemoradiation experienced complete pathologic response

TABLE 84.5 Clinical Trials for Establishing the Role of Multimodal Therapy Versus Surgery Alone for Esophageal Cancer

A. NEOADJUVANT CHEMORADIATION PLUS SURGERY VERSUS SURGERY ALONE

CLINICAL TRIAL	SIZE	HISTOLOGY	INTERVENTION/CONTROL	KEY OUTCOMES IN INTERVENTION GROUP
CROSS (2012)	366	Adenocarcinoma (75%) SCC (23%)	I: Carboplatin/paclitaxel with concurrent RT (41.4 Gy, 23 fractions), then surgery C: Surgery alone	• Higher rate of R0 resection (92% vs. 69%) • 49% rate of pathologic complete response for SCC, 29% for adenocarcinoma • Longer median OS (49.4 months vs. 24 months) • Higher 5-year OS (47% vs. 34%)
NEOCRTEC (2018)	451	SCC	I: Vinorelbine/cisplatin with concurrent RT (40 Gy, 20 fractions), then surgery C: Surgery alone	• Higher rate of R0 resection (98.4% vs. 91.2%) • 43.2% rate of pathologic complete response • Longer median OS (100.1 months vs. 66.5 months) • Prolonged DFS (100.1 months vs. 41.7 months) • Higher 5-year OS (59.9% vs. 49.1%) in long-term follow-up study (2021)

B. PERIOPERATIVE CHEMOTHERAPY PLUS SURGERY *VERSUS* SURGERY ALONE

CLINICAL TRIAL	SIZE	HISTOLOGY	INTERVENTION/CONTROL	KEY OUTCOMES IN INTERVENTION GROUP
MAGIC (2006)	503	Adenocarcinoma (*majority stomach*, 25% esophageal and EGJ)	I: Pre- and post-op epirubicin, cisplatin, 5-FU C: Surgery alone	• Improved DFS • Improved 5-year OS (36% vs 23%)
FNCLCC ACCORD 07 (2011)	224	Adenocarcinoma (75% esophageal and EGJ)	I: Pre- and post-op cisplatin, 5-FU C: Surgery alone	• Improved 5-year OS (38% vs 24%) • 8% decrease in distant recurrence rates • Improved R0 resection rate (84% vs 74%)

C, Control; *CROSS,* Chemoradiotherapy for Oesophageal Cancer Followed by Surgery; *DFS,* disease-free survival; *I,* intervention; *NEOCRTEC,* Neoadjuvant Chemoradiotherapy for Esophageal Cancer; *OS,* overall survival; *RT,* radiation therapy; *SCC,* squamous cell carcinoma.

(ypT0N0M0) significantly more than patients with adenocarcinoma (49% vs. 29%). Expectedly, nodal positivity was higher in patients with surgery alone compared with the preoperative chemoradiation group (75% vs. 31%). At a median follow-up duration of 45 months, patients receiving preoperative chemoradiation had significantly longer median OS (49.4 months) than patients undergoing surgery alone (24 months). The 1-, 2-, 3-, and 5-year OS rates were 82%, 67%, 58%, and 47%, respectively, in the preoperative chemoradiation arm compared with 70%, 50%, 44%, and 34%, respectively in the surgery-alone arm.[76] After a minimum follow-up of 24 months, the overall rate of recurrence was 35% in the preoperative chemoradiation arm compared with 58% with surgery alone. Additionally, preoperative chemoradiation significantly reduced locoregional recurrence from 34% to 14%.[77] Importantly, preoperative chemoradiation did not negatively affect postoperative health-related quality of life.[78]

Although the CROSS trial established the survival benefit for preoperative chemoradiation therapy with a paclitaxel and carboplatin regimen, subsequent trials examined other chemotherapy regimens. The single-arm SWOG trial demonstrated the efficacy and safety of preoperative FOLFOX (5-fluorouracil and oxaliplatin) combined with radiation. PROTECT is an ongoing randomized phase II trial that is directly comparing preoperative chemoradiation with FOLFOX versus carboplatin/paclitaxel regimens, both with concurrent RT (41.4 Gy). The Cancer and Leukemia Group B (CALGB) 9781 prospective phase III trial investigated the preoperative regimen of cisplatin and 5-FU (CF) and 50.4 Gy followed by surgery versus surgery alone, which also showed 5-year OS benefit (39% vs. 16%).[79]

Although the majority of patients in the previous trials had adenocarcinoma, the NEOCRTEC trial (2018) exclusively enrolled patients with locally advanced SCC and compared safety and survival outcomes of preoperative chemoradiation plus surgery versus surgery alone. The preoperative chemoradiation arm had a higher R0 resection rate (98.4% vs. 91.2%), improved median OS (100.1 months vs. 66.5 months), and prolonged DFS. Incidences of postoperative complications were similar between both groups.[80]

In summary, the collective findings of these randomized control trials consistently showed that preoperative chemoradiation improves OS compared with surgery alone among patients with locally advanced esophageal cancer for both adenocarcinoma and SCC.

Given that pCR was found in a substantial portion of patients who had undergone neoadjuvant chemoradiation and given the morbidity of esophagectomy, some have questioned the necessity of surgical resection. Two early studies that compared patients who received neoadjuvant chemoradiation followed by surgery versus additional chemoradiation found no difference in OS.[81,82] In a more recent study involving patients who achieved clinical complete response to chemoradiation, active surveillance was associated with similar progression-free survival and OS to that observed with immediate esophagectomy.[83] Several phase III studies are investigating variations of a selective surgery approach, including the most recently published SANO trial (2025), which investigated the option for active surveillance for patients with clinical complete response after neoadjuvant chemoradiation. Clinical complete response was defined by no tumor detected by endoscopic biopsies, EUS, and PET/CT at 6 and 12 weeks following completion of neoadjuvant therapy, after which patients were then randomized to active surveillance or esophagectomy. The study found that OS after active surveillance was noninferior compared with standard surgery after two years.[84] Despite these findings, active surveillance remains controversial as the ability to accurately determine complete clinical response remains limited: Concordance between clinical complete response and pCR is only ~30%.[85] Developing methods, such as ctDNA, for detecting minimal residual disease could help fill this knowledge gap.

Perioperative Chemotherapy

Since the initial trials that showed survival benefit with neoadjuvant chemotherapy (e.g., the MRC and UK OEO2 studies previously mentioned), several notable studies have established the effectiveness of perioperative chemotherapy (i.e., neoadjuvant and adjuvant) for the treatment of locally advanced esophageal cancer (see Table 84.5).

One of the first landmark trials was the phase III MRC Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial (2006), which used a regimen of epirubicin, cisplatin, and 5-FU (ECF) pre- and postoperatively (three cycles each). It should be noted that the majority of enrolled patients had adenocarcinoma of the stomach, but there was a subgroup with EGJ and lower esophageal cancer. Moreover, only 50% of patients were able to complete the prescribed course of adjuvant therapy. Regardless, the results demonstrated improved DFS and OS, with better 5-year OS of 36% with perioperative chemotherapy versus 23% with surgery alone. Preoperative chemotherapy also reduced tumor size in all patients but had limited effects on R0 resection rates. The limitation of this trial was that only 25% of participants had EGJ or lower esophageal adenocarcinoma; therefore, the results could not be extrapolated to esophageal cancer with certainty.[86]

Therefore, the French FNCLCC ACCORD 07 FCCD 9703 trial (2011) randomized 224 patients, 75% of whom had adenocarcinoma of the distal esophagus or EGJ, to perioperative CF and surgery compared with surgery alone. The researchers found a significant OS benefit (38% vs. 24%) in the perioperative chemotherapy group compared with surgery alone and an 8% reduction in distant recurrence rates. This trial also showed a significantly improved R0 resection rate in the perioperative chemotherapy group compared with surgery alone (84% vs. 74%). Although this trial was prematurely terminated because of low accrual, it argued for CF as a viable neoadjuvant regimen.[87]

The phase II/III FLOT4 trial (2019) received significant attention because it compared two different perioperative chemotherapy regimens—FLOT (four cycles pre- and postoperative of fluorouracil, leucovorin, oxaliplatin, docetaxel) to standard ECF (the MAGIC trial regimen)—in patients with resectable gastric or EGJ adenocarcinoma (Table 84.6). The results showed that FLOT was associated with a significantly higher rate of pCR than ECF (16% vs. 6%). FLOT was also associated with a reduction in the percentage of patients who experienced at least one grade 3 or 4 adverse event (40% vs. 25% in the ECF group). The phase III portion of the trial showed that median OS was increased in the FLOT group compared with the ECF group (50 months vs. 35 months), as was 5-year OS (45% vs. 36%). The percentage of patients with serious chemotherapy-related adverse events was the same (27% in both groups).[88] Given these findings, FLOT is now considered the standard care for esophageal adenocarcinoma patients, with the NCCN recommending its use for patients with good performance status. FOLFOX is recommended for patients with good to moderate performance status.[19]

For esophageal SCC, the Japan Clinical Oncology Group (JCOG) 9907 trial (2012) confirmed the benefits of using perioperative CF-based chemotherapy regimen, which improved the R0 resection rate and OS (55% vs. 43%).[89] As a result, neoadjuvant CF-based chemotherapy has become the standard treatment for locally advanced esophageal SCC in Japan.

Based on these large clinical trials, neoadjuvant therapy, whether given as preoperative chemoradiation or perioperative chemotherapy, confers survival advantage compared with surgery alone for patients with locally advanced esophageal cancer. Which strategy is better (see Table 84.6)? The Neoadjuvant Trial in Adenocarcinoma

TABLE 84.6 Clinical Trials Comparing Different Multimodal Therapies for Esophageal Cancer

A. COMPARING DIFFERENT PERIOPERATIVE CHEMOTHERAPY REGIMENS

CLINICAL TRIAL	SIZE	HISTOLOGY	INTERVENTION/CONTROL	KEY OUTCOMES IN INTERVENTION GROUP
FLOT4 (2019)	265	Adenocarcinoma (gastric, GEJ)	I: FLOT (fluorouracil, leucovorin, oxaliplatin, docetaxel) C: Epirubicin, leucovorin, oxaliplatin (MAGIC regimen)	• Higher rate of pCR (16% vs. 6%) • Improved median OS (50 vs. 35 months) • Improved 5-year OS (45% vs. 36%)

B. NEOADJUVANT CHEMORADIATION VERSUS PERIOPERATIVE CHEMOTHERAPY

CLINICAL TRIAL	SIZE	HISTOLOGY	INTERVENTION/CONTROL	KEY OUTCOMES IN INTERVENTION GROUP
NEO-AEGIS (2023)	377	Adenocarcinoma (esophagus, GEJ)	C: Modified MAGIC or FLOT regimen (perioperative chemotherapy) I: CROSS regimen (preoperative chemoRT)	• Similar number of deaths in both arms • Similar 3-year OS (55% vs. 57%) • Pathologic endpoints (pathologic complete response, R0 resection, nodal downstaging) favored preoperative chemoRT
ESOPEC (2025)	438	Adenocarcinoma (esophagus, GEJ)	C: FLOT regimen (perioperative chemotherapy) I: CROSS regimen (preoperative chemoRT)	• Improved 3-year OS with FLOT (57.4%) compared to CROSS (50.7%) • Lower 90-day mortality after surgery with FLOT (3.1%) compared to CROSS (5.6%) • Higher rate of adverse events in FLOT group

C, Control; *chemoRT,* chemoradiation therapy; *CROSS,* Chemoradiotherapy for Oesophageal Cancer Followed by Surgery; *GEJ,* gastroesophageal junction; *I,* intervention; *MAGIC,* Medical Research Council Adjuvant Gastric Infusional Chemotherapy; *NEO-AGIS,* Neoadjuvant Trial in Adenocarcinoma of the Esophagus and Esophago-Gastric Junction International Study; *OS,* overall survival; *pCR,* pathologic complete response.

of the Esophagus and Esophago-Gastric Junction International Study (Neo-AEGIS, 2023) directly compared preoperative chemoradiation (CROSS regimen) to perioperative chemotherapy (modified MAGIC or FLOT regimen) in 377 patients with esophageal adenocarcinoma. At a median follow-up of 38.8 months, median OS was 48 months in the perioperative chemotherapy group and 49.2 months in the preoperative chemoradiation group with 3 year OS of 55% and 57%, respectively. All pathologic end points (pCR rate and R0 resection status) favored preoperative chemoradiation.[90] Though underpowered and incomplete, Neo-AEGIS suggested noninferiority of perioperative chemotherapy to preoperative chemoradiation. Subsequently, the ESOPEC trial (2025) made a similar comparison by evaluating the effectiveness of perioperative chemotherapy (using FLOT) versus preoperative chemoradiation (per the CROSS regimen) in 438 patients with esophageal adenocarcinoma. In contrast to Neo-AEGIS, this trial found a greater survival benefit with perioperative FLOT than with preoperative chemoradiation (CROSS), with 3-year OS being 57.4% compared to 50.7%, respectively. While longer term results are to be seen, both strategies remain viable options for patients of resectable locoregional adenocarcinoma.[91]

Definitive Chemoradiation

Definitive chemoradiation is indicated for nonsurgical candidates (patients who decline surgery or patients unable to tolerate major surgery). It is also recommended for patients with cT4b (unresectable) esophageal cancer and, in some cases, can facilitate surgical resection (salvage esophagectomy) in select patients who have good response.[19] For inoperable disease, although radiation is a method of local control, chemotherapy is thought to sensitize tumor cells to radiation while also contributing to control of micrometastatic disease. The Radiation Therapy Oncology Group (RTOG) 85-01 was an early randomized trial that compared chemoradiation (with CF) versus radiation alone at a standard 50.4-Gy dose.[92] Patients in the chemoradiation arm showed significant improvement in median survival (14 months vs. 9 months) and 5-year OS (27% vs. 0%) and also had a lower incidence of local failure (47% vs. 65%). Multiple trials (the follow-up INT-0123, ARTDECO, and CONCORDE) have shown no benefit of radiation dose escalation above 50 Gy.[64,93,94] Cisplatin with either docetaxel or paclitaxel is the recommended regimen for definitive chemoradiation.

Posttreatment Management and Outcomes

Postoperative management is based on surgical margins, pathologic tumor stage, histology, and previous treatment. Patients who received neoadjuvant chemotherapy as part of a perioperative protocol should complete the adjuvant cycles of chemotherapy once recovered from surgery. For patients who had undergone neoadjuvant chemoradiation and R0 resection found to have residual disease on final pathology, adjuvant nivolumab is recommended based on the CheckMate 577 trial.[68] Other than this, the components of postoperative management have not been established in randomized trials specifically for esophageal cancer. Instead, available evidence for the use of postoperative chemoradiation and chemotherapy is extrapolated from trials for gastric cancer. For patients who had not received neoadjuvant therapy, capecitabine/oxaliplatin or FOLFOX are acceptable options. The INT-0116 trial demonstrated effectiveness of postoperative chemoradiation in patients with resected gastric or EGJ adenocarcinoma who had not received preoperative therapy.[95–97]

All patients should be followed in a systematic manner after completion of multimodal therapy. However, surveillance strategies after successful therapy remain variable and controversial, with no high-level evidence to guide algorithms that balance benefits and risks. The NCCN guidelines provide stage-specific strategies based on currently available evidence from retrospective studies and expert consensus. Approximately 90% of recurrences occur within the first 2 years of local therapy, and most recurrences occur as distant disease. Although routine esophageal cancer-specific surveillance is generally not recommended for more than 5 years after end of treatment, exceptions should be considered based on risk factors.[19]

In general, follow-up for asymptomatic patients should include complete history and physical examination every 3 to 6 months in the first 2 years and then every 6 to 12 months for years 3 to 5. A complete blood count, chemistry profile, upper endoscopy with biopsy, and cross-sectional imaging should be performed based on stage of treated disease and as clinically indicated.[19]

Although Tis-T1aN0 disease have prognoses that approximate a noncancer cohort, T1b disease has comparatively worse prognosis. Thus, surveillance recommendations vary according to depth of invasion as well as the treatment modality. Endoscopic surveillance is recommended for early-stage disease (Tis, T1a, T1b) in patients treated with ER/ablation. Imaging studies should additionally be considered for T1b patients.[19]

Locoregional recurrence is relatively uncommon with neoadjuvant therapy followed by esophagectomy, so endoscopic surveillance is not indicated (although endoscopy should be considered if symptomatic). Instead, distant recurrence is the more common pattern.[98–99] Therefore, these patients are followed with cross-sectional imaging every 6 months for up to 2 years and annually for up to 5 years. On the other hand, locoregional recurrence is common after definitive chemoradiation, making upper endoscopy a logical surveillance strategy in these patients in addition to cross-sectional imaging.[100]

Unresectable Locally Advanced, Recurrent, and Metastatic Disease

In patients with locoregional recurrence after definitive chemoradiation therapy, salvage esophagectomy is an option if the patient is deemed medically fit for surgery and if the recurrence is resectable. For patients who have had prior esophagectomy with recurrent disease, treatment options include concurrent chemoradiation, reoperation, systemic therapy (chemotherapy, targeted therapy, or immunotherapy), or palliative management/best supportive care. For those who are medically unable to tolerate major surgery and those with unresectable or metastatic recurrence, palliative management and best supportive care are always indicated.[19]

Systemic therapy, which includes chemotherapy and targeted therapy or immunotherapy (depending on MSI or MMR, PD-L1, and HER2 status), is also an option but should only be offered to patients with good performance status. For both esophageal adenocarcinoma and SCC, cisplatin with 5-FU is the standard first-line treatment option for patients with locally advanced disease who are not candidates for surgery or definitive chemoradiation. Adding docetaxel and variants of this regimen have demonstrated better tolerability and outcomes. Oxaliplatin plus capecitabine is noninferior to CF, possibly with a more manageable toxicity profile. Nonetheless, chemotherapy has limited efficacy (OS less than 12 months) in most patients with advanced disease. In HER2-positive patients, trastuzumab combined with first-line chemotherapy has become standard therapy in advanced-stage esophageal adenocarcinoma. In patients with MMR deficiency and PD-L1–positive status, ICIs (anti-PD1 antibody drugs) are now indicated as first-line treatment for advanced-stage esophageal SCC in combination with chemotherapy or ipilimumab and as monotherapy in the second-line setting.[19]

Palliative and best supportive care are aimed at mitigating suffering and improving quality of life for patients and their caregivers, regardless of disease stage. In advanced or metastatic disease, such care can provide symptom relief and improve overall quality of life and may result in life prolongation, especially when a multimodality interdisciplinary approach is employed. Dysphagia and obstruction can be palliated with self-expanding metal stents. Palliative radiation is also an option. Additionally, enteral feeding access by jejunostomy or gastrostomy tube (if no resection is planned) may be needed to provide adequate nutrition and hydration.[19]

SUMMARY AND CONCLUSION

Esophageal cancer is a global disease with high mortality that remains a complex and challenging disease to treat. A multimodal therapeutic approach involving chemotherapy, surgery, and radiation has been shown by multiple large trials to confer the best chances for survival. Insight into the role of immunotherapy is forthcoming. Although survival outcomes have markedly improved over the past 40 to 50 years as a result of significant advances in treatment strategies and tools, OS remains low. There is still much to unravel about the biology of the disease and much to be distilled regarding which patients would benefit most from the armamentarium of treatment options and strategies.

Al-Batran SE, Homann N, Pauligk C, et al. Perioperative chemotherapy with fluorouracil plus leucovorin, oxaliplatin, and docetaxel versus fluorouracil or capecitabine plus cisplatin and epirubicin for locally advanced, resectable gastric or gastro-oesophageal junction adenocarcinoma (FLOT4): a randomised, phase 2/3 trial. *Lancet*. 2019;393(10184):1948-1957.

In the footsteps of the MAGIC trial establishing a role for perioperative chemotherapy, this trial sought to compare a new regimen (FLOT) to the MAGIC regimen to see if it could also increase overall survival with potentially a better toxicity profile. Although the toxicity profiles were similar for both groups, overall survival proved to be better with the FLOT regimen than with the MAGIC regimen. As such, FLOT has become the standard-of-care regimen in patients with good functional status.

Cunningham D, Alum WH, Stenning SP, et al. Perioperative chemotherapy versus surgery alone for resectable gastroesophageal cancer. *N Engl J Med*. 2006;355(1):11-20.

Also known as the MAGIC trial, this is one of the early landmark trials establishing a role for perioperative chemotherapy in the treatment of resectable gastric and esophagogastric cancer, showing survival advantage in patients who received perioperative chemotherapy and surgery versus surgery alone. Although not definitively applicable to esophageal cancer at the time because that patient cohort was the minority population, it laid the foundation for subsequent trials of multimodal therapy with different drug regimens and majority esophageal cancer patients.

Kelly RJ, Ajani JA, Kuzdzal J, et al. Adjuvant nivolumab in resected esophageal or gastroesophageal junction cancer. *N Engl J Med*. 2021;384(13):1191-1203.

This was an important trial for two reasons: (1) establishing a role for immunotherapy in the treatment of resectable esophageal cancer and (2) presenting an adjuvant option for patients treated with neoadjuvant chemoradiation and then surgery who had residual pathologic disease and thus were at higher risk of recurrence. This trial showed that this group of patients benefitted from adjuvant nivolumab in terms of improved DFS.

National Comprehensive Cancer Network. *NCCN Guidelines Version 2.2023 Esophageal and Esophagogastric Junction Cancers*. 2023. https://www.nccn.org/guidelines/guidelines-detail?category=1&id=1433

The NCCN provides guidelines and stage-based treatment algorithms that oncologists reference to help real-world decision-making. The guidelines are developed by a multi-institutional committee of oncologists from all fields and updated regularly. In addition to flowcharts, the guideline provides in-depth discussions of all aspects of cancer care.

Rice TW, Patil DP, Blackstone EH. 8th Edition AJCC/UICC staging of cancers of the esophagus and esophagogastric junction: application to clinical practice. *Ann Cardiothorac Surg*. 2017;6(2):1191-1130.

This article comprehensively reviews all aspects of the 8th edition AJCC/Union for International Cancer Control (UICC) staging for esophageal and esophagogastric junction cancers, including the rationale and data supporting the changes made from the previous edition. It elaborates on how the staging system can and should be applied in clinical practice.

van Hagen P, Hulshof MC, van Lanschot JJ, et al. Preoperative chemoradiotherapy for esophageal or junctional cancer. *N Engl J Med*. 2012;366:2074-2084.

Also known as the CROSS trial, this is an early landmark trial that established the now standard-of-care for neoadjuvant chemoradiation therapy for resectable esophageal cancer.

CHAPTER 85

The Acute Abdomen

Kaitlin A. Ritter, Mary I. Junak, John E. Scarborough, and Vanessa P. Ho

OUTLINE

Differential Diagnosis
Evaluation
  History
  Physical Examination
  Laboratory Studies
Diagnostic Studies and Imaging
  Ultrasound
  Plain Radiography
  Computed Tomography
  Magnetic Resonance Imaging
  Diagnostic Procedures
Preparation for Emergency Operation
Preoperative Counseling
Nonoperative Management
Special Patient Populations
  Sex-Specific Considerations
  Pregnancy
  Geriatrics
  Immunocompromised Individuals
  Critically Ill Patients
  Post–Bariatric Surgery
Summary

The abdomen is compartmentalized into intraperitoneal and retroperitoneal spaces. Critical to the acute abdomen, the intraperitoneal space houses organs such as the stomach, small intestines, transverse colon, liver, spleen, and appendix. In contrast, the retroperitoneal space contains the kidneys, pancreas, ascending and descending parts of the colon, and major vessels. Abdominal pain can originate from any of these organs because of varied etiologies such as inflammation, obstruction, perforation, or ischemia.

Vascular supply to the abdomen is primarily from the abdominal aorta, which bifurcates into the common iliac arteries at the level of the fourth lumbar vertebra. Emerging from the aorta to supply the abdominal organs are major branches: the celiac trunk, the superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA). These vessels, in turn, branch out to supply blood to the abdominal organs (Fig. 85.1). Compromise in the perfusion from any of these arteries, as seen in conditions like mesenteric ischemia, can precipitate acute abdominal symptoms. Furthermore, the venous return is predominantly through the portal system into the inferior vena cava, and obstruction or thrombosis in these veins can also contribute to acute abdominal pathology.

The physiologic basis for abdominal pain is rooted in the intricate innervation of the peritoneum. The peritoneum is divided into the parietal and visceral components. The parietal peritoneum, lining the abdominal wall, is innervated by somatic nerves that correspond to the dermatomes of the overlying skin. As a result, any irritation or inflammation of this layer produces sharp, well-localized pain. In contrast, the visceral peritoneum, which envelops the abdominal organs, is supplied by autonomic nerves. Irritation of the visceral peritoneum yields dull, poorly localized pain, often described as "crampy" or "achy." Therefore, the nature and localization of abdominal pain can offer invaluable clues regarding the underlying pathology, be it arising from the abdominal wall or the internal organs themselves. Visceral inflammation can evolve to parietal inflammation, explaining the classic abdominal pain patterns in inflammatory diseases such as appendicitis: vague periumbilical pain that localizes to the right lower quadrant as the parietal peritoneum becomes involved in the inflammatory process.

DIFFERENTIAL DIAGNOSIS

The diagnosis of an "acute abdomen" is in and of itself not actually a specific medical or surgical condition, but rather a collection of symptoms, physical examination findings, and diagnostic workup that suggests an acute process within or even external to the abdominal cavity that frequently requires operative management. The threshold for labeling the onset of abdominal pain as acute (vs. subacute or chronic) is generally, though arbitrarily, set at 1 week. The differential diagnosis for an acute abdomen is broad and can involve multiple organ systems. A list of frequent causes of an acute abdomen can be seen in Table 85.1.

Narrowing of this differential relies heavily on thorough clinical history taking and physical examination. The history must include the patient age, sex, and associated signs and symptoms and must incorporate the patient's past medical and surgical history. Certain diagnoses are more common in specific age groups because the likelihood of developing various processes will change over the course of a patient's life. Diverticulitis, biliary tract disease, and peptic ulcers are common causes of acute pain in adults, but not in younger patients. Even within pediatric populations, disease frequency varies across childhood (Table 85.2). Females of childbearing age have a unique set of gynecologic-related conditions that must be considered (see the later section "Special

Patient Populations"). Similarly, geriatric populations are at risk for atypical presentation of common conditions because of age-related changes in muscle and nerve fibers, which can alter motor and sensory functions.[1] An understanding of a patient's prior abdominal procedures and operations may also provide clues to possible diagnoses because prior surgeries, infections, and cancers can change the differential.

Although a consult for an acute abdomen often sparks concern for an underlying surgical process, several medical conditions can also produce these findings.[2] Attention to potential medical confounders is equally important for the evaluating surgeon so as to avoid the unnecessary surgical intervention. Acute pancreatitis, sickle cell crisis, diabetic ketoacidosis, spontaneous bacterial peritonitis, and pyelonephritis are just a few of the common medical processes that can mimic an acute surgical pathology (Table 85.3). Careful attention to a patient's history can often provide insight into these conditions.

EVALUATION

History

Although advances in laboratory studies and imaging help facilitate more accurate diagnoses, a comprehensive history remains the first key step in workup of the acute abdomen. Careful attention

TABLE 85.3 Nonsurgical Causes of Acute Abdomen in Adults

Metabolic/Endocrine

- Diabetic ketoacidosis
- Hyperosmolar hyperglycemic state
- Addison disease
- Porphyria
- Familial Mediterranean fever

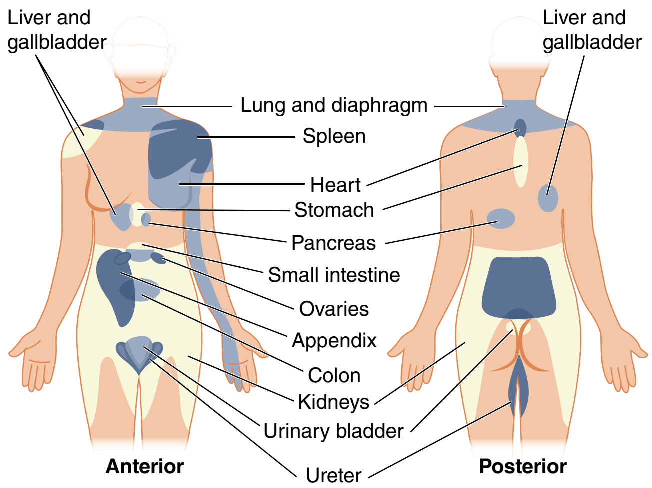

FIGURE 85.2 Cutaneous sites of referred pain from visceral structures. (From Anderson MK. *Foundations of Athletic Training.* 6th ed. Lippincott Williams & Wilkins; 2016, Figure 6-1.)

to the onset, character, location, quality, and duration of the abdominal pain can provide key clues to the underlying etiology. As discussed earlier, the two-part innervation of the abdominal cavity by the parietal and visceral peritoneum allows for often unique presentations of various pathologies[3] (Fig. 85.2). One such example includes irritation of the diaphragm by free intraperitoneal air resulting in referred pain to the shoulder because of the phrenic nerve's anatomic connections to the brachial plexus.[4,5] Thus, although the nature of the patient's abdominal pain is an important element of the history, other nonabdominal pain should be evaluated as well. In addition to abdominal pain referred to nonabdominal locations, it is also possible for extraabdominal processes to present with abdominal pain, such as occurs when acute myocardial infarction manifests as upper abdominal pain.[6]

Once an assessment of pain has been performed, the next step should include an evaluation of any other associated symptoms the patient is experiencing. Nausea, vomiting, diarrhea, or lack of bowel function can all provide important insight into an underlying gastrointestinal process. Fever, chills, and recent sick contacts can be suggestive of an infective process. Assessing for accompanying symptoms can help guide the diagnostic workup, including the need for specific imaging adjuncts.

An understanding of the patient's past medical and surgical history is also important in the initial assessment. Certain causes of an acute abdomen are more likely with various medical conditions and can raise these diagnoses higher on the differential. Vascular processes such as ruptured abdominal aortic aneurysmal disease or acute mesenteric ischemia are of higher likelihood in a patient with chronic vasculopathy who remains an active smoker then in a healthy college student. Similarly, a patient's past surgical history can provide insight into the leading diagnosis. In the immediately postoperative patient, a unique set of causes of acute abdominal pain exist, such as a missed enterotomy or anastomotic leak. For females, questions regarding menstrual history, including last menstrual period, history of endometriosis, prior pregnancy/sexually transmitted diseases (STDs), recent sexual activity, and contraceptive use, are also essential.

Finally, a review of the patient's current medications, allergies, and social history (including tobacco, alcohol, and illicit drug use) should also be performed. Patients on steroids or immunosuppressive medications can often present with blunted physiologic responses to pain and infection and thus may require a higher degree of suspicion for more uncommon disease processes.[7] Potential noncompliance with prescribed medications may also suggest certain pathologies. The person with diabetes who has not been taking their insulin may present with diabetic ketoacidosis, whereas the patient with atrial fibrillation who has not been taking their prescribed anticoagulant may present with abdominal pain because of an embolic phenomenon.

Physical Examination

A thorough and complete physical examination, including abdominal inspection, palpation, percussion, and auscultation, can provide critical information in the assessment of a patient with an acute abdomen.[8] Inspection or visual assessment of the abdomen should pay attention to distention, scars/skin abnormalities, masses/hernias, or striae/enlarged veins. Skin changes such as periumbilical (Cullen sign) or flank (Grey Turner sign) bruising can alert an astute provider to intraabdominal or retroperitoneal hemorrhage. Surgical scars can provide a road map for a patient's past intraabdominal conditions and suggest unique pathologies applicable only to postoperative patients, such as incisional hernias and adhesive small bowel obstruction. Examination of the groin is an absolute necessity when performing an abdominal examination. As an adjunct to the abdominal examination, genital, rectal, and pelvic examinations also have a role in the evaluation of patients. Genital processes such as testicular/ovarian torsion, prostatitis, pelvic inflammatory disease, and pregnancy-related conditions can all result in acute abdominal pain. The rectal examination can also provide significant information, including the presence of gastrointestinal bleeding, constipation, or obstructing masses or lesions. Although not always required, these examination elements can provide key diagnostic information in the right clinical scenarios. Evaluation of these areas should only be deferred if there is low clinical suspicion.

Percussion followed by palpation of the abdomen, with a focus on areas of tenderness, referred pain, rebound, and involuntary guarding, can be instructive. Additionally, the surgeon should palpate for potential intraabdominal masses, abdominal wall defects, shifting dullness, or pulsative vascular structures. Palpable irreducible hernias with abdominal distention and tympany can reveal acute obstructive processes. Attention should be paid to the area of maximal tenderness because patients may initially endorse generalized abdominal pain but subsequently localize to a specific area upon careful examination. This localization and correlation with underlying anatomic structures can help narrow the differential diagnosis. Most patients with an acute abdomen will present with at least some of the classic findings of peritonitis, including involuntary guarding, abdominal rigidity, and rebound tenderness. Involuntary guarding can be difficult to determine, as patients will often voluntarily tense their abdominal wall muscles in response to palpation. Having the patient lie supine with their legs bent and soles of their feet on the bed will help to relax the abdominal musculature and allow for more accurate examination. Rebound tenderness, which occurs when the release of pressure from the abdominal wall causes worsening of the patient's pain, is caused by irritation of the parietal peritoneum and can thus be indicative of peritonitis. A special note should be made for complaints of severe pain without concomitant tenderness, referred to as *pain out of proportion to exam,* as this may herald organ ischemia rather than perforation. Careful assessment of vascular risk factors in these patients may raise the suspicion for acute mesenteric ischemia.

Auscultation, although a common examination maneuver taught in medical school, has limited utility in the assessment of the acute abdomen. Traditionally students are taught to listen for an absence of bowel sounds, or *high-pitched tinkling,* as indications of an obstruction. Studies of the accuracy of this maneuver have found poor sensitivity and specificity; consequently, its clinical use has gone by the wayside.[9] Auscultation for vascular abnormalities such as bruits, although technically possible, also has low specificity and sensitivity. Any data gathered from abdominal auscultation should be used in conjunction with the remainder of the physical examination.

In addition to the traditional abdominal examination, several eponymously named maneuvers and techniques have been developed, with variable correlation with specific disease processes (Table 85.4). One of the most commonly encountered (and often

TABLE 85.4 **Eponymous Abdominal Examination Signs and Maneuvers**

NAME	SIGN/MANEUVER	CLINICAL CORRELATION
Aaron sign	Pain or pressure in epigastrium with firm pressure applied to McBurney point	Referred pain in epigastrium from acute appendicitis
Balance sign	Dullness to percussion in the left upper quadrant/flank with shifting dullness in right flank	Splenic rupture/hematoma
Blumberg sign	Pain with removal of pressure rather than application of pressure to the abdomen	Peritoneal inflammation/peritonitis
Carnett sign	Continued or increased abdominal pain when abdominal wall muscles are tensed	Abdominal wall source of pain
Chandelier sign	Extreme pelvic pain with movement of the cervix	Pelvic inflammatory disease
Cullen sign	Periumbilical bruising	Hemoperitoneum
Danforth sign	Shoulder pain on inspiration	Irritation of the diaphragm by hemoperitoneum
Fothergill sign	Abdominal wall mass that does not cross midline and is palpable when rectus is contracted	Rectus sheath hematoma
Grey Turner sign	Discoloration/bruising of flanks between the last rib and the top of the hip	Retroperitoneal hemorrhage, severe acute pancreatitis
Hannington-Kiff sign	Absent adductor reflex in thigh with presence of positive patellar reflex	Compression of obturator nerve caused by obturator hernia
Howship-Romberg sign	Pain of inner thigh on internal rotation of the hip	Obturator hernia
Iliopsoas sign	Elevation of extended leg against resistance is painful	Retrocecal acute appendicitis
Murphy sign	Respiratory arrest during inspiration with palpation of the right upper quadrant	Acute cholecystitis
Obturator sign	Pain on passive internal rotation of the hip when the right knee is flexed	Pelvic abscess or inflammatory mass, pelvic appendicitis
Ransohoff sign	Yellow discoloration of umbilical region	Ruptured common bile duct
Rovsing sign	Pain felt in right lower quadrant when palpating the left lower quadrant	Acute appendicitis
Ten Horn sign	Pain in the right iliac fossa caused by gentle traction of right testicle	Acute appendicitis

misunderstood) findings is Murphy's sign of acute cholecystitis. With the patient supine, they are asked to exhale as the examiner palpates the right subcostal region. The patient is then asked to take a deep breath. As the diaphragm pushes the abdominal contents caudally during this inhalation, an acutely inflamed gallbladder will come in contact with parietal peritoneum underlying the examiner's hand. The pain of contact will result in the involuntary pausing of the patient's inhaled breath. Although potentially useful examination adjuncts, these eponymous findings must be used in the context of a complete history and physical examination because most do not provide sufficient sensitivity or specificity to allow for a definitive diagnosis on their own.[10]

Although the abdominal examination is a key feature of the physical examination for patients with a concern for an acute abdomen, evaluation of other body systems is also important. Patients with acute abdominal pain will often present with signs of systemic toxicity, including tachycardia, diaphoresis, and pallor. Increased work of breathing in the absence of pulmonary wheezing or rales can be suggestive of a compensatory respiratory process, and abdominal sepsis with acidosis can likewise manifest as a respiratory issue. Similarly, other nonabdominal examination findings can indicate an extraabdominal process masquerading as an acute abdomen. In a patient who presents with epigastric pain, the finding of distant heart sounds and diminished auscultation of bilateral lung bases may indicate the presence of an acute coronary syndrome rather than an intraabdominal process. To avoid such diagnostic errors, a full physical assessment should be performed in any patient who presents with acute abdominal pain.

Laboratory Studies

Laboratory results often help to provide additional clarity regarding the clinical condition of a patient who presents with an acute abdomen. In general, a complete blood count (CBC), basic metabolic panel (BMP), and serum lactate should be obtained in most patients who present with acute abdominal pain and whose history and physical examination support the existence of an acute abdominal disease process. The white blood cell count found on the CBC can be either elevated or reduced in many acute intraabdominal infectious processes. Further analysis of the white blood cell count using a cell differentiation test can demonstrate elevation of the neutrophil count (so termed *a left shift*), supporting the potential diagnosis of bacterial infection.[11] Low hematocrit or hemoglobin may suggest a hemorrhagic source of abdominal pathology, whereas elevation of the hematocrit/hemoglobin may alternatively suggest intravascular volume depletion caused by an intraabdominal process. Platelets are an acute-phase reactant that undergoes agonistic synergism with other acute-phase reactants such as C-reactive protein, and thus a reactive thrombocytosis may be found with many acute inflammatory/infectious conditions.[12] Similarly, the presence of acidosis on the BMP or an elevated serum lactate level can be indicative of a metabolic derangement with its own broad differential, ranging from dehydration, to evolving sepsis, to end-organ ischemia. The addition of an arterial blood gas in patients with lactic acidosis may help to further delineate underlying metabolic/respiratory disturbances.

Further laboratory evaluation should be based on the patient's clinical history, examination, and a differential diagnosis that has been narrowed by history and physical examination. Organ-specific tests such as liver function tests (LFTs) or serum amylase/lipase can be used to support the diagnosis of conditions such as cholecystitis, choledocholithiasis, or pancreatitis. A urinalysis can assist in the diagnosis of cystitis, pyelonephritis, or nephrolithiasis. *Clostridioides difficile* toxin assay and an infectious stool panel, including ova/parasites, may be obtained in patients with the correct historical risk factors, such as recent antibiotic use or foreign travel. β–Human chorionic gonadotropin (β-HCG) is an important laboratory test in any females of reproductive age because pregnancy and pregnancy-related complications must always be considered in the differential of acute abdominal pain in sexually active females of childbearing age. In addition to the use of laboratory tests for diagnostic purposes, an active type and screen and updated coagulation studies are essential for patients in whom surgical intervention is anticipated.

DIAGNOSTIC STUDIES AND IMAGING

After a thorough medical history and physical examination, and in conjunction with laboratory studies, diagnostic imaging may be obtained. There are a wide variety of imaging options for the evaluation of abdominal pathology, ranging from noninvasive and low-cost to potentially harmful and expensive. A comprehensive but precise differential should be established before obtaining imaging so that the most appropriate modality can assist in establishing a definitive diagnosis. Although the initial instinct is to reflexively order cross-sectional imaging for any patient with a concerning abdominal examination, careful clinical workup and a thorough differential diagnosis can often spare these patients nondiagnostic tests and unnecessary radiation exposure. Relatively low-cost, low-risk, and time-saving imaging modalities such as ultrasound and plain film radiographs can offer significant information to narrow a differential diagnosis.

Ultrasound

Ultrasound uses high-frequency sound waves emitted from piezoelectric crystals in the transducer probe and allows for visualization of underlying structures because of the variable reflective and impedance properties of different tissues. This form of imaging does not require ionizing radiation and can provide rapid assessment for multiple acute intraabdominal pathologies. Ultrasound has moderate to excellent sensitivity for some disease processes and is the diagnostic gold standard for others.[13] Transabdominal, transthoracic, and transvaginal approaches all exist, each with their own unique set of views and identifiable pathologies. In the hands of an experienced operator, ultrasound can assess multiple organ systems, including the hepatic/biliary, vascular, gastrointestinal, and genitourinary systems (Fig. 85.3). Increasingly, point-of-care ultrasound (sometimes referred to as *POCUS*) has expanded within the emergency department and the intensive care unit, allowing for even more rapid image assessment of the acute abdomen.[14] Associated with high diagnostic accuracy, POCUS imaging has also been demonstrated to decrease the time to diagnosis and to be associated with a financial cost savings.[15,16] Limitations of ultrasound include the inability to penetrate bowel gas for visualization of deeper structures and the technical challenge for the patient with a larger body habitus, which reduces the ultrasound wave penetration and picture quality.

Plain Radiography

Plain film radiographs of the abdomen are another commonly used imaging modality. Although the diagnostic accuracy of plain film radiographs is significantly lower than that of other imaging studies, there are still several specific disease pathologies where they can provide significant information (Fig. 85.4). In the case of a perforated hollow viscus, an upright abdominal radiograph can

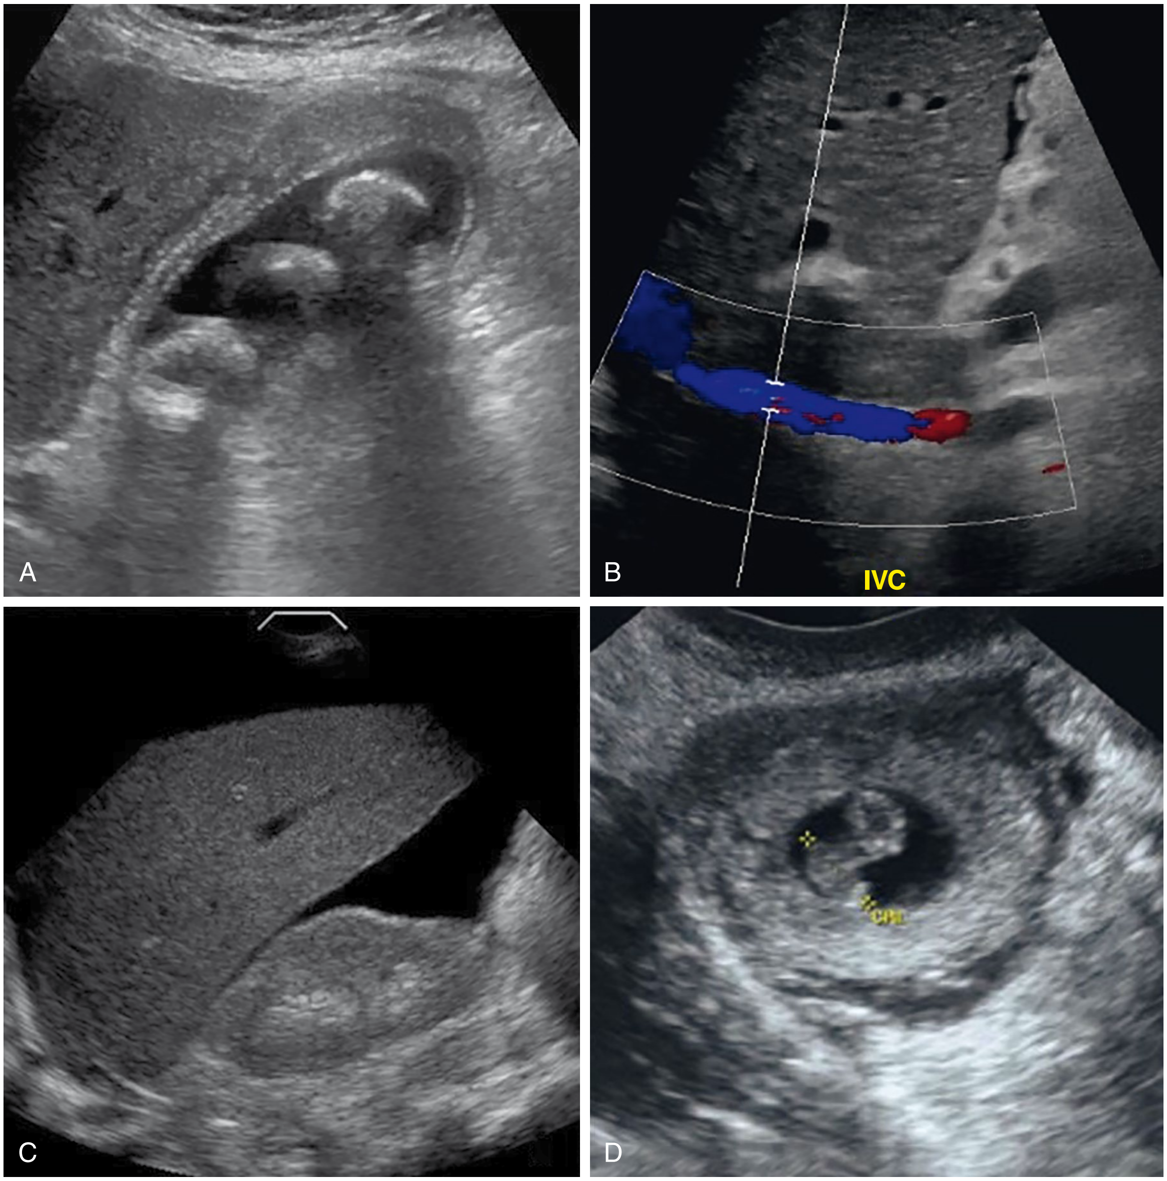

FIGURE 85.3 Ultrasound images of various abdominal structures. (A) Right upper quadrant ultrasound demonstrated gallbladder wall thickening, hyperechoic gallstones, and findings consistent with acute cholecystitis. (B) Right upper quadrant ultrasound of liver and inferior vena cava *(IVC)* demonstrating cirrhotic liver morphology and calculation of IVC size for volume assessment. (C) Right upper quadrant ultrasound demonstrating free fluid between liver and kidney consistent with hemoperitoneum. (D) Pelvic ultrasound demonstrating ectopic pregnancy. (C, From American Institute of Ultrasound in Medicine; American College of Emergency Physicians. Ectopic pregnancy: ultrasound diagnosis and management. In: Rizk B, Puscheck E, eds. *Ultrasonography in Gynecology.* Cambridge University Press; 2014:139-154.)

demonstrate free air under the diaphragm and allow for earlier surgical consultation and more timely intervention. A dilated stomach and small bowel loops with air-fluid levels and paucity of colonic gas can be demonstrated on abdominal radiograph and is suggestive of a small bowel obstruction. Although a patient with a bowel obstruction will still likely require cross-sectional imaging to determine the etiology, early abdominal radiography will allow for the placement of a nasogastric tube and help reduce the risk of potential aspiration while the patient lies flat for a CT scan. Similarly, massive colonic dilation with the classic radiographic findings of the “bent inner tube” or “coffee bean sign” are heralds for cecal or sigmoid volvulus and result in prompt surgical/gastrointestinal consult. An abdominal radiograph can also assist in identification of nephrolithiasis and gastrointestinal/rectal foreign bodies.

Computed Tomography

In the modern era, the CT scan has become the primary diagnostic tool in the workup of abdominal pain. Allowing for complete visualization of all intrathoracic and intraabdominal structures,

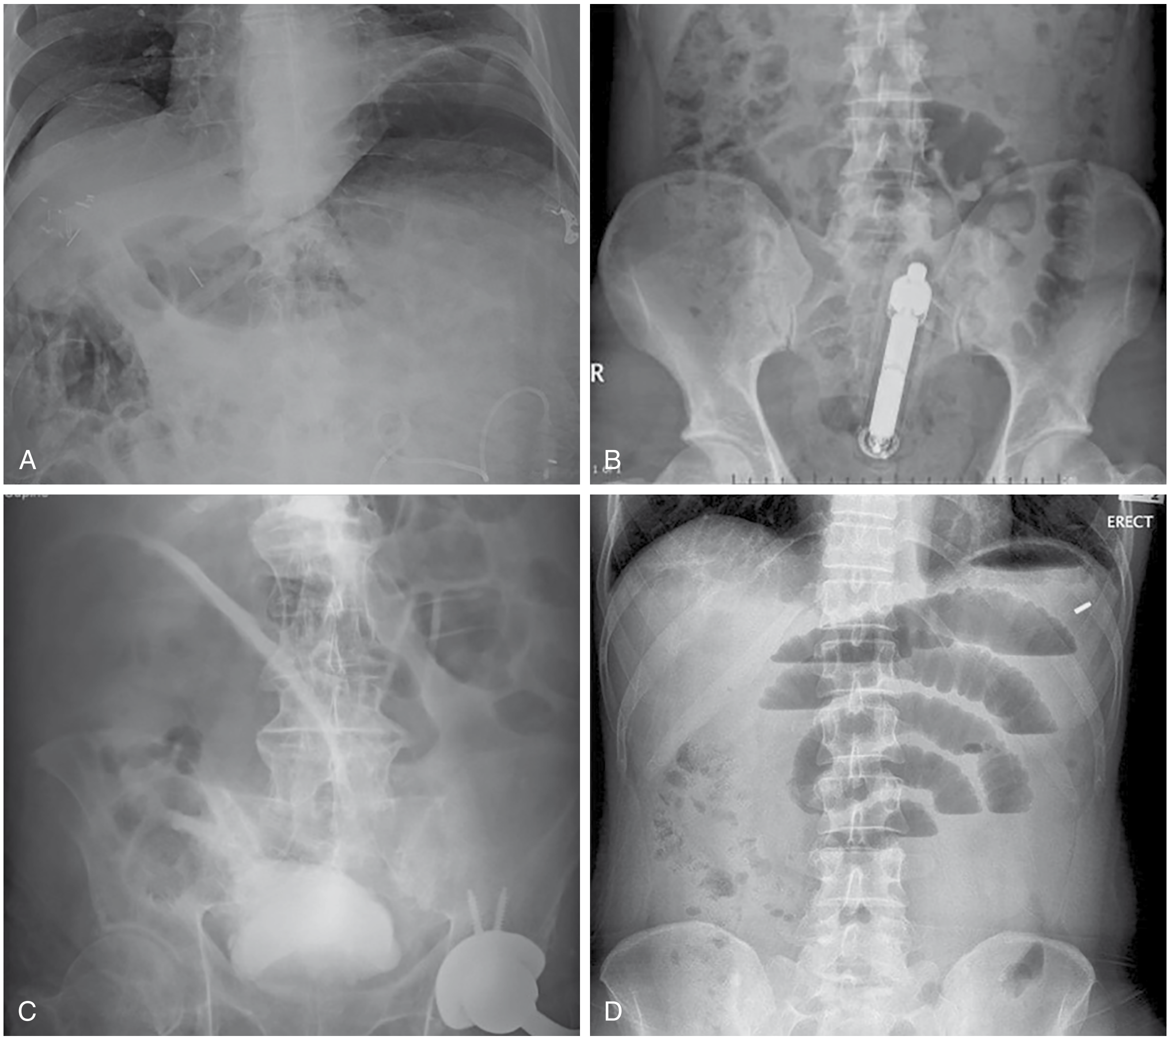

FIGURE 85.4 Plain film radiographs of acute abdominal pathologies. (A) Kidney, ureter, and bladder with free air under the diaphragm suggestive of a perforated viscus. (B) Radiograph with rectal foreign body. (C) Abdominal radiography with classic bent inner tube sign suggestive of colonic volvulus. Accessed on October 31, 2023.)

the CT scan trades the need for ionizing radiation with the benefit of high-quality pictures and less dependence on operator skill. Not all CT scans are created equal, however, and in the workup of the acute abdomen, an understanding of the various contrast options and timing protocols is critical to ensure your scan is maximally diagnostic while minimizing the radiation exposure to the patient. A table of the average radiation dosing from various imaging modalities can be seen in Table 85.5.

The simplest of CT scans includes a noncontrasted scan, which is useful for several disease processes including nephrolithiasis, acute stroke, and evaluation of chronic lung disease. In efforts to save patients the dose of IV contrast and the increasingly outdated fear of contrast-induced kidney injury,[17] workup of the acute abdomen in the emergency department often starts with a noncontrasted CT. Although noncontrasted studies have demonstrated moderate diagnostic accuracy,[18,19] a blinded retrospective review of contrasted versus noncontrasted CT scans in the emergency department for the workup of acute abdominal pain found a 30% reduction in diagnostic accuracy for noncontrasted scans.[20] Consequently, use of IV contrast and the theoretical risk of acute kidney injury or potential hypersensitivity reactions should be weighed against the leading diagnoses and the additional radiographic information able to be obtained from a contrasted scan.

The addition of oral or rectal contrast is another consideration for a CT scan. Oral contrast can add a significant delay because the scans must be timed to allow for the contrast to be delivered to the patient, for the patient to ingest the contrast, and then a predetermined amount of time allotted to allow the contrast to pass from the stomach and through the gastrointestinal tract. Time delays of over an hour have been reported in some series with the addition of oral contrast,[21] and several large series evaluating the omission of oral contrast for workup of acute abdominal pain have found no significant loss in diagnostic accuracy.[22,23] The one exception in favor of the use of oral contrast is evaluation for a gastrointestinal perforation or concern for anastomotic leak. The presence of oral contrast leakage has a high specificity for a perforation and can aid in localization but has a low sensitivity.[24] Often other ancillary signs such as wall discontinuity, fat stranding, and extraluminal gas will accompany a perforation or leak, obviating the need for oral contrast. Rectal contrast, which is given in a

TABLE 85.5 Relative Radiation Dose Estimates for Abdominal Radiographic Imaging

	ADULT EFFECTIVE DOSE RANGE	PEDIATRIC EFFECTIVE DOSE RANGE
Ultrasound abdomen	0 mSv	0 mSv
Plain film radiograph abdomen	0.1–1 mSv	0.03–0.3 mSv
CT abdomen pelvis without IV contrast	1–10 mSv	0.3–3 mSv

Abridged from Expert Panel on Gastrointestinal Imaging; Scheirey CD, Fowler KJ, Therrien JA, et al. ACR Appropriateness Criteria acute nonlocalized abdominal pain. *J Am Coll Radiol.* 2018;15(11S):S217-S231.

CT scan and administered through a temporary rectal tube under hydrostatic pressure, has no time delay but can lead to patient discomfort without significant increase in diagnostic accuracy.

A final consideration related to CT imaging is the use of IV contrast, which is specifically timed or phased to capture distribution throughout the vascular system. Timing of the contrast to allow for opacification of the mesenteric arterial and venous systems can be especially helpful for specific vascular etiologies of abdominal pain. CT angiography (CTA) is a technique used to visualize the vasculature throughout the body, as imaging is obtained at the time of peak arterial or venous enhancement. This can be useful when evaluating select patients with acute abdominal pain. For example, if a patient presents with signs and symptoms concerning for mesenteric ischemia or aortic dissection, prompt evaluation with CTA can help guide further management and is superior to other imaging modalities. In these instances, it is important to maintain a high degree of clinical suspicion to ensure the appropriate form of CT is obtained. One study found that for patients with acute SMA occlusion, in-hospital mortality was 42% for patients who underwent contrast-enhanced CT as opposed to 90% for those without contrasted imaging.[25] In addition to vascular abnormalities, CTA can visualize the health of the bowel, as diminished wall enhancement and mesenteric stranding can suggest bowel ischemia (Fig. 85.5).

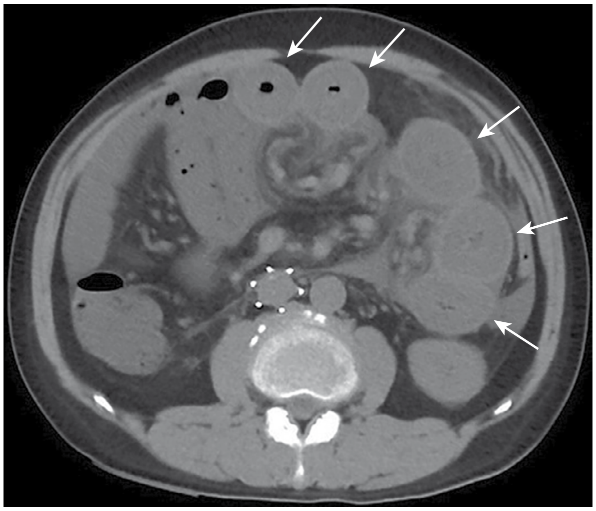

FIGURE 85.5 Contrast-enhanced computed tomography with hypoenhancement of the bowel wall concerning for intestinal ischemia. The *arrows* indicate segments of bowel wall with thickening and hypoenhancement concerning for intestinal ischemia.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an additional technology available for the workup of an acute abdomen, but comes with several limitations. The benefits of MRI stem from its high-quality imaging of the entire abdominal cavity without the use of ionizing radiation, making it an attractive option for any patient but specifically for high-risk groups such as children and pregnant patients. For example, in pregnant patients with acute appendicitis, MRI was found to have a greater than 90% sensitivity and specificity for the diagnosis, which is far superior to other nonradiating imaging modalities such as ultrasound.[26] Furthermore, one study found that in the over 200 pregnant females with acute appendicitis who were enrolled, there was not a single instance where the appendix was not visualized on MRI.[27] Limitations include its relatively high cost compared with other cross-sectional imaging modalities; long scan time (30–90 minutes vs. seconds to minutes for a CT scan); inability to use for patients with specific metal implants, pacemakers/defibrillators, and history of retained metallic foreign bodies; and the need for patients to remain still for extended periods. It is for these reasons that the American College of Radiology recommends selective use of MRI in appropriate clinical scenarios for the workup of the acute abdomen.[28]

Diagnostic Procedures

In addition to laboratory and imaging evaluation, several diagnostic procedures can aid in determining the etiology of a patient's acute abdomen. Insertion of a nasogastric tube with saline lavage and aspiration of blood contents can guide a clinician to an upper gastrointestinal bleed. Although studies have found no difference in clinical patient outcomes for those who undergo lavage, this procedure was associated with a shorter time to endoscopy and can help guide management pathways.[29]

For a patient with concern for intraabdominal hypertension, using a bladder catheter hooked up to a pressure transducer can be used to measure intraabdominal pressure (IAP). With the bladder drained and the patient supine, 25 mL of saline is instilled into the bladder, and the pressure is then measured with the transducer zeroed at the iliac crest at the midaxillary line (for pediatric patients, 1 mL/kg up to 25 kg with a minimum of at least 3 mL saline is instilled). Normal IAP should be between 5 and 7 mm Hg in the supine and paralyzed patient. Elevations in pressures can be seen with abdominal obesity, pregnancy, upright positioning, and Valsalva maneuvers. Intraabdominal hypertension is diagnosed with sustained elevations of the IAP >12 mm Hg, and abdominal compartment syndrome is defined as sustained IAP >20 mm Hg with evidence of end-organ dysfunction.[30] Prompt diagnosis and intervention are necessary to avoid ongoing or permanent organ dysfunction in these patients.

With advances in the quality and technology of CT scanners, CTA has largely replaced the need for traditional catheter-based angiography to evaluate for intraabdominal vascular issues.[31] Although CTA has increasingly become the gold standard, use of catheter-based angiography does still play a role in diagnosis of acute pathologies. Patients who are hemodynamically unstable because of a suspected vascular lesion (such as a history of a known abdominal aortic aneurysm) may be taken emergently to the catheterization laboratory for dual diagnosis and therapeutic intervention. This approach, however, requires specific clinical scenarios and the rapid availability of an angiography operating room and team. Additionally, if the CTA is nondiagnostic in the setting of a suspicious lesion, angiography may be used as a second-line test to help confirm or disprove the diagnosis. In the modern era, however, catheter-based angiography is uncommonly used as a first-line diagnostic modality and is instead increasingly being reserved for therapeutic interventions.

In select situations, laparoscopy may be used as a diagnostic modality. The use of laparoscopy for diagnostic purposes has been explored for clinical situations where the diagnosis remains unclear, but most studies that have evaluated this topic did not use cross-sectional imaging as part of their diagnostic workup.[32-34] Laparoscopy may assist in situations where disease pathologies present similarly such as acute appendicitis and acute gynecologic issues in females of reproductive age. Diagnostic imaging in these scenarios can often be limited because of the adjacent nature of the appendix and gynecologic structures, with inflammation and fluid further confounding the identification of the offending organ.[35] Similarly, other clinical scenarios, such as an acute abdomen in a patient with a history of bariatric surgery, can often benefit from diagnostic laparoscopy in situations where the cross-sectional imaging is nondiagnostic.[36]

Trauma patients represent a unique cohort for whom the use of laparoscopy as a standard part of diagnostic workup has been well studied. In patients with blunt abdominal trauma, high rates of missed blunt bowel injury and diaphragmatic injury have been reported with CT imaging. In patients with the appropriate clinical symptoms, trauma mechanism, or presence of free fluid on CT imaging without concomitant injury, diagnostic laparoscopy should be considered.[37] For patients with penetrating trauma who are nonperitoneal and have equivocal peritoneal violation on local wound exploration, diagnostic laparoscopy can be used to help identify peritoneal violation. This allows for assessment of any intraabdominal injuries while reducing the risk of a negative laparotomy.[38]

PREPARATION FOR EMERGENCY OPERATION

Patients with an acute abdomen can vary tremendously in their hemodynamic stability and overall state of health. Unlike elective procedures where risk factors can be optimized preoperatively, the acute abdomen often requires emergent operative intervention, leaving little time for preparation for surgery. A preoperative assessment of a patient's cardiovascular and respiratory risk factors is important, and simple tests such as an electrocardiogram or chest radiograph may provide relevant information without any significant delay in intervention. The benefits of further workup or optimization must be weighed against the increased morbidity and mortality associated with a delay in treatment.

All patients should undergo basic resuscitation while awaiting operative intervention, including the placement of sufficient intravenous (IV) access, infusion of IV fluids or blood products as required, and correction of electrolyte abnormalities. Obtaining a preoperative type and screen (and a crossmatch if significant blood loss is possible), coagulation panel, blood cultures, and lactate can assist with the intraoperative and postoperative resuscitation. Most patients with an acute abdomen will require antibiotic administration, and initial selection should be targeted at organisms most likely involved in the disease process. In acute abdominal emergencies, gram-negative enteric organisms and anaerobes represent the most common offenders, and broad-spectrum therapy is indicated for initial therapy. Guidance on antibiotic selection should be informed by your institution's microbiology and specific antibiogram and population studies.[39] Antibiotics should be narrowed based on intraoperative findings and organism sensitivities as soon as possible. Additional support devices such as nasogastric tubes, Foley catheters, and central/arterial lines should be placed as required depending on the clinical scenario.

The postoperative level of care, specifically the need for an intensive care unit (ICU) bed, should be anticipated and arranged to minimize postoperative delays in transfer and ongoing resuscitation. If possible, a preoperative discussion with the operating room nursing staff and anesthesiology team about the patient's clinical condition, anticipated interventions, and potentially required equipment/medications can help facilitate a smooth operative course.

PREOPERATIVE COUNSELING

Preoperative counseling is an essential part of preparing a patient for the operating room. Frequently, the exact diagnosis and extent of the required operation are not known preoperatively. Preparing the patient and their family for the wide potential of surgical interventions and postoperative issues before surgery can help streamline the patient's future care. Operative interventions such as open versus laparoscopic approaches, bowel resections, ostomies, need for temporary abdominal closure, and repeat operations are just some considerations to be discussed. Postoperative concerns such as need for prolonged ICU care, ventilator dependence, renal failure/dialysis, need for tracheostomy, and feeding tubes are also important issues to discuss because many patients have strong opinions about advanced life support devices.

These discussions are all an essential part of informed consent, which should include a review of the purpose, risks, benefits, and alternatives (including nonoperative management) of surgery. This process should be an open and engaged conversation, allowing for expression of any concerns or questions. If the patient has a living will or designated medical power of attorney, identifying this person before surgery or discussing the patient's desired code status can help guide your postoperative medical decision-making. For patients with an anticipated long postoperative or ICU admission, the preoperative consent may be the only opportunity to speak to a patient about the possibility of a prolonged intubation, and if appropriate, the patient's preferences about a tracheostomy or a feeding tube should be discussed and the patient's desired surrogate decision-maker should be identified. Discussing the potential operative and postoperative course and setting expectations with the patient and their family help build a therapeutic alliance and build a culture of patient-centered care.

NONOPERATIVE MANAGEMENT

Although most cases of an acute abdomen require surgical intervention, there are several distinct pathologies for which nonoperative management is a viable and sometimes preferred approach. The use of selective nonoperative management hinges on the patient's hemodynamic parameters. Any patient with hemodynamic instability from their abdominal process is unlikely to be successfully managed nonoperatively, and prompt surgical care should not be delayed in these cases. In medically complex patients who require further optimization before surgical intervention, nonoperative management can be a bridge while comorbidities are addressed.

In select cases, nonoperative management may entail only fluid resuscitation and antibiotic therapy. Treatment with antibiotics has become an appropriate alternative to surgery in some instances. The CODA trial followed adult patients with acute uncomplicated appendicitis, with and without an appendicolith, who were randomized to treatment with antibiotics versus appendectomy. The study found that antibiotics were noninferior to appendectomy for the treatment of appendicitis. Specifically, among the patients who received antibiotics, 29% ultimately underwent appendectomy within 90 days.[40] It should also be noted that nonoperative management of acute appendicitis has been associated with higher rates of abscess formation, readmission, and overall cost of care.[41] Acute uncomplicated diverticulitis is another common entity that is now often treated with a short course of oral antibiotics. The benefit of nonoperative management in patients with this condition is the avoidance of emergent surgery, which has up to a 40% complication rate.[42] For patients with a contained perforation of their sigmoid diverticulitis without peritonitis, management with nil per os and IV antibiotics was found to have a 71.4% to 94% success rate. This approach spared patients operative intervention, bowel resection, and need for stoma creation.[43]

Alternative options for nonoperative treatment of the acute abdomen include percutaneous drainage, often performed by an interventional radiologist. Cases of intraabdominal abscess from perforated appendicitis or diverticulitis can resolve with antibiotics and percutaneous drainage, which mitigates the risk of an often technically challenging emergency surgery. Percutaneous drainage is also a reasonable option in patients who are poor surgical candidates. For example, a percutaneous cholecystostomy tube is an appropriate treatment for critically ill patients with acute cholecystitis who would not withstand cholecystectomy. Although percutaneous drainage may be a reasonable option in some patients, it is associated with procedure-related pain, increased hospital length of stay, radiation from repeated imaging, and potential delayed diagnosis of malignancy.[44]

The selective use of nonoperative management should be predicated upon the patient's overall clinical condition and in discussion with the patient regarding their preferences and the risks of non-operative management and entered into with an understanding that failure of nonoperative management will require surgical intervention. For some patients, nonoperative management despite the high risk for failure is a purposeful choice to align their treatment with their overall goals of care. A trial of medical therapy is started, and if signs point to failure, patients may choose to pursue no further escalation of care and transition to hospice measures. Again, joint decision-making and open communication with the patient and their families are critical for these approaches.

SPECIAL PATIENT POPULATIONS

Sex-Specific Considerations

The presentation of the acute abdomen can be influenced by sex-specific anatomic structures and related pathologies. In female patients, understanding potential etiologies related to gynecologic structures is crucial. Factors such as menstrual and sexual history can offer diagnostic clues. Conditions can include endometriosis, ovarian torsion, and ectopic pregnancy. Endometriosis presents with cyclical pain, which corresponds to menstrual cycles; ovarian torsion can present with severe pelvic pain and adnexal mass; and ectopic pregnancy can present with a positive pregnancy test or a missed period along with abdominal pain and vaginal bleeding. Likewise, in male patients, pathologies of the testes and epididymis, such as testicular torsion or epididymitis, should be considered when evaluating acute abdominal and scrotal pain.

Pregnancy

Evaluation of the pregnant patient presents unique challenges, as acute abdominal pain in pregnancy can stem from both obstetric and nonobstetric causes. Differential conditions in the obstetric realm can include placental abruption, round ligament pain, HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) syndrome, uterine and ovarian torsion, and uterine rupture.[45] However, nonobstetric causes such as appendicitis and cholecystitis also occur during pregnancy, and anatomic changes that can occur with the growing uterus can change the location and characteristics of pain. For example, appendicitis occurs in approximately 100 of every 100,000 births; these patients have significantly higher rates of peritonitis, sepsis, septic shock, and postoperative complications.[46] However, operative management remains the preferred treatment because medical management in appendicitis is associated with a higher rate of adverse outcomes. A careful consideration of diagnostic testing should be employed in the pregnant patient, with preference for methods that reduce ionizing radiation such as ultrasound and MRI. However, if ionizing radiation is necessary to provide expeditious care for the mother, it is important to note that delays in diagnosis and treatment can lead to adverse outcomes in both the mother and fetus, and a CT scan should be performed if the benefits outweigh the risks. Radiation risk is dependent on two factors: the cumulative radiation dosage and the fetal age at exposure; fetal mortality is highest within the first 2 weeks of conception, and the fetus is most vulnerable to teratogenesis between 10 and 17 weeks. Expert consensus is that the risk of ionizing radiation–induced fetal harm is low at 50 mGy or less, and the usual fetal radiation dose of a routine CT scan of the abdomen and pelvis is around 25 mGy.[45]

Geriatrics

The older patient with acute abdominal pain also poses unique challenges. Concomitant with age and aging, patients are more likely to present with increased rates of comorbidities, more severe comorbidities, more functional limitations, and an increased risk of baseline frailty. Frailty is the increased vulnerability resulting from aging-related decline in reserve and function, which reduces an individual's ability to cope with stressors[47] and is a more superior predictor of outcomes than age alone.[48] In addition, the presence of polypharmacy and other preexisting medical conditions can cloud the diagnostic picture. Older patients have a higher risk of surgical complications and mortality when an operation is pursued compared with younger patients with the same diseases and presentations.[49]

Immunocompromised Individuals

Patients with compromised immune systems represent a particularly vulnerable group. An immunocompromised state can stem from underlying diseases such as human immunodeficiency virus (HIV), organ transplantation, chemotherapy, or other immunosuppressive medications. In these patients, common abdominal pathologies may present with muted or atypical presentations, leading to diagnostic delays. Recent or chronic steroid use can also alter the body's response to infection and mask peritonitis, requiring a higher level of suspicion. The immunocompromised patient is also more susceptible to postoperative complications, progression of sepsis, and infection from atypical pathogens.

Critically Ill Patients

In critically ill patients, rapid diagnosis is vital but can also be challenging. Patients may present with altered mental status, making the patient history unreliable, or may be intubated at the time of surgery consultation. Critical illness from other causes can also lead to abdominal pathologies. Examples of this include acalculous cholecystitis, bowel ischemia from high-dose vasopressors, or acute colonic pseudoobstruction (Ogilvie syndrome).

Post–Bariatric Surgery

Unique differential diagnoses need consideration in patients who have a history of bariatric surgery. The anatomy is often altered because of procedures such as gastric bypass, sleeve gastrectomy, or adjustable gastric banding, leading to nontraditional presentations of common abdominal conditions. Anastomotic leaks, internal hernias, and complications related to marginal ulceration (such as bleeding or perforation) must additionally be considered when evaluating the post–bariatric surgery patient. Postoperative gallstone formation can also occur as a side effect of rapid weight loss.

SUMMARY

Evaluation and treatment of the acute abdomen necessitates a systematic and methodical approach, combining a detailed history and physical examination, pertinent laboratory studies, and diagnostic imaging to narrow what often starts as a very broad list of differential diagnoses. Diagnostic and therapeutic strategies should be individualized, taking into consideration the specific diagnosis, the unique biology and physiology of the patient, and the wishes of the patient and their surrogate decision-makers if needed. Notably, special patient populations bring to the table distinct challenges and considerations. Evaluation of the acute abdomen remains the most fundamental and quintessential skill for the general surgeon.

ANATOMY

Gross Anatomy

Divisions

The stomach is derived from the embryonic primitive gut tube, beginning as a dilation during the fourth to fifth week of gestation in the caudal portion. The embryonic stomach is invested by two mesenteries: dorsal (which becomes the gastrosplenic, gastrocolic, and gastrophrenic ligaments) and ventral (which becomes the hepatoduodenal and gastrohepatic ligaments of the lesser omentum and the falciform ligament). By the seventh week of gestation, the stomach rotates 90 degrees in the clockwise direction along its longitudinal axis and dilates, with a disproportionate elongation of the greater curvature into its normal anatomic shape and position. The 90-degree rotation results in the left vagus nerve being ventral and the right vagus nerve being dorsal; rotation also creates the omental bursa (or lesser sac).

The stomach is fixed at the gastroesophageal (GE) junction and pylorus. The most proximal region of the stomach is the cardia. The cardiac orifice (or cardioesophageal junction) is the opening of the esophagus into the stomach. Immediately proximal to the cardia is the physiologically competent lower esophageal sphincter. The fundus is to the left of the cardia and represents the superior-most part of the stomach. The fundus is floppy and distensible. The angle of His, also referred to as the *esophagogastric angle,* is an important anatomic feature formed between the fundus and the left margin of the esophagus. The angle of His forms an anatomic sphincter, helping to prevent GE reflux. The body of the stomach represents the largest portion and is also referred to as the *corpus.* The body is bounded on the right by the relatively straight lesser curvature and on the left by the longer greater curvature. At the angularis incisura, the lesser curvature abruptly angles to the right. The body of the stomach ends here and the antrum begins. Distally, the pylorus connects the distal stomach (antrum) to the proximal duodenum (Fig. 86.1).

The left lateral section of the liver covers a large portion of the stomach anteriorly. The gastrohepatic ligament connects the liver to the lesser curve of the stomach and contains the right and left gastric arteries. Posteriorly, the stomach is bounded by the diaphragm, left kidney, pancreas, aorta, and celiac trunk. Inferiorly, the stomach is attached to the transverse colon via the gastrocolic ligament, which contains the right and left gastroepiploic vessels. Superiorly, the GE junction is found approximately 2 to 3 cm below the diaphragmatic esophageal hiatus in the horizontal plane of the seventh chondrosternal articulation. The gastrosplenic

ligament attaches the proximal greater curvature to the spleen and contains the short gastric arteries.

Blood Supply

The celiac artery provides the majority of the blood supply to the stomach (Fig. 86.2). There are four main arteries—the left and right gastric arteries along the lesser curvature and the left and right gastroepiploic arteries along the greater curvature, with the left gastric artery being the largest. In addition, a substantial quantity of blood may be supplied to the proximal stomach by the short gastric arteries (which arise from the splenic artery) and the inferior phrenic artery. The left gastric artery is one of the three branches of the celiac trunk, along with the common hepatic artery and splenic artery. The right gastric artery typically arises from the proper hepatic artery. The left gastroepiploic artery originates from the splenic artery, and the right gastroepiploic artery originates from the gastroduodenal artery. The extensive anastomotic connections between these major vessels ensure that, in most cases, the stomach will survive if three out of four arteries are ligated, provided that the arcades along the greater and lesser curvatures are not disturbed. In general, the veins of the stomach parallel the arteries. The left gastric (coronary) and right gastric veins usually drain into the portal vein or at the confluence of the superior mesenteric and splenic veins. The left gastroepiploic vein drains into the splenic vein. The right gastroepiploic vein typically joins with the superior right colic and anterior superior pancreaticoduodenal veins to form Henle's trunk, which then drains into the superior mesenteric vein, though multiple anatomic variations of Henle's trunk exist.[1]

Lymphatic Drainage

The lymphatic drainage of the stomach parallels the vasculature and drains into four zones of lymph nodes. The superior gastric group drains lymph from the upper lesser curvature into the left gastric and paracardial nodes. The suprapyloric group of nodes drains the antral segment on the lesser curvature of the stomach

into the right suprapancreatic nodes. The pancreaticolienal group of nodes drains lymph high on the greater curvature into the left gastroepiploic and splenic nodes. The inferior gastric and subpyloric group of nodes drains lymph along the right gastroepiploic vascular pedicle. All four zones of lymph nodes drain into the celiac nodes and eventually into the thoracic duct. Although these lymph nodes drain different areas of the stomach, gastric cancers may metastasize to any of the four nodal groups. In addition, the extensive submucosal plexus of lymphatics accounts for the fact that there is frequently microscopic evidence of malignant cells several centimeters from gross disease.

Innervation

As shown in Fig. 86.3, the extrinsic innervation of the stomach is both parasympathetic (via the vagus nerve) and sympathetic (via the celiac plexus). The vagus nerve originates in the vagal nucleus in the floor of the fourth ventricle and traverses the neck in the carotid sheath to enter the mediastinum, where it divides into several branches around the esophagus. These branches coalesce above the esophageal hiatus to form the left and right vagus nerves. It is not uncommon to find more than two vagal trunks at the distal esophagus. At the GE junction, the left vagus is anterior and the right vagus is posterior.

The left vagus gives off the hepatic branch to the liver and continues along the lesser curvature as the nerve of Latarjet. The so-called *criminal nerve of Grassi* is the first branch of the right posterior vagus nerve; it is recognized as a potential cause of recurrent ulcers when it is not divided during a vagotomy. The right vagus nerve gives off a branch to the celiac plexus and continues posteriorly along the lesser curvature. A truncal vagotomy is performed above the celiac and hepatic branches of the vagi, whereas a selective vagotomy is performed below. A highly selective vagotomy is performed by dividing the crow's feet to the proximal stomach while preserving the innervation of the antral and pyloric parts of the stomach. Most (90%) of the vagal fibers are afferent, carrying stimuli to the brain. Efferent vagal fibers originate in the dorsal nucleus of the medulla and synapse with neurons in the myenteric and submucosal plexuses. These neurons influence gastric motor function and gastric secretion. In contrast, the sympathetic nerve supply comes from T5–T10, traveling in the splanchnic nerve to the celiac ganglion. Postganglionic fibers travel with the arterial system to innervate the stomach.

The line of division for selective vagotomy is shown; this is below the hepatic and celiac branches. (From Mercer D, Liu T. Open truncal vagotomy. *Oper Tech Gen Surg.* 2003;5:80-85.)

The intrinsic or enteric nervous system of the stomach consists of neurons in Auerbach and Meissner autonomic plexuses. In these locations, cholinergic, serotoninergic, and peptidergic neurons are present. The exact function of these neurons is not fully elucidated. Nevertheless, numerous neuropeptides have been localized to these neurons, including acetylcholine, serotonin, substance P, calcitonin gene–related peptide, bombesin, cholecystokinin (CCK), and somatostatin.

Gastric Morphology

The stomach is covered by peritoneum, which forms the outer serosa of the stomach. Below this is the thicker muscularis propria, or muscularis externa, which is composed of three layers of smooth muscles. The middle layer of smooth muscle is circular and is the only complete muscle layer of the stomach wall. At the pylorus, this middle circular muscle layer becomes progressively thicker and functions as a true anatomic sphincter. The outer muscle layer is longitudinal and predominates in the distal two-thirds of the stomach. Within the layers of the muscularis externa is a rich plexus of autonomic nerves and ganglia, called *Auerbach myenteric plexus.* The submucosa lies between the muscularis externa and the mucosa and is a collagen-rich layer of connective tissue that forms the strongest layer of the gastric wall. In addition, it contains the rich anastomotic network of blood vessels and lymphatics as well as the Meissner plexus of autonomic nerves. The mucosa consists of surface epithelium, lamina propria, and muscularis mucosae. The muscularis mucosae is on the luminal side of the submucosa and is probably responsible for the rugae that greatly increase the stomach's epithelial surface area. The lamina propria represents a small connective tissue layer and contains capillaries, vessels, lymphatics, and nerves necessary to support the surface epithelium. It also marks the microscopic boundary between invasive and noninvasive gastric carcinoma.

Gastric Microscopic Anatomy

Gastric mucosa consists of simple columnar epithelia interrupted by gastric pits containing one or more gastric glands. The cellular populations (and functions) of the cells forming this glandular epithelium vary based on their location in the stomach (Table 86.1). The glandular epithelium is divided into cells that secrete products into the gastric lumen for digestion (parietal cells, chief cells, mucus-secreting cells) and cells that control function (gastrin-secreting G cells, somatostatin-secreting D cells). In the cardia, the mucosa is arranged in branched glands and the pits are short. In the fundus and body, the glands are more tubular and the pits are longer. In the antrum, the glands are more branched. The luminal ends of the gastric glands and pits are lined with mucus-secreting surface epithelial cells, which extend down into the necks of the glands for variable distances. In the cardia, the glands are predominantly mucus-secreting. In the body, the glands are mostly lined from the neck to the base with parietal and chief cells. There are a few parietal cells in the fundus and

TABLE 86.1 **Gastric Cell Types, Location, and Function**

CELL TYPE	LOCATION	FUNCTION
Parietal	Body	Secretion of acid and intrinsic factor
Mucus	Body, antrum	Mucus
Chief	Body	Pepsin
Surface epithelial	Diffuse	Mucus, bicarbonate, prostaglandins
Enterochromaffin-like	Body	Histamine

Enteric neurons	Diffuse	Calcitonin gene–related peptide, others
Endocrine	Body	Ghrelin

proximal antrum, but none in the cardia or prepyloric antrum. The endocrine G cells are present in greatest quantity in the antral glands.

PHYSIOLOGY

The principal function of the stomach is to prepare ingested food for digestion and absorption in the small intestine. Receptive relaxation of the proximal stomach with ingestion of food enables the stomach to function as a storage organ. This relaxation enables liquids to pass easily from the stomach along the lesser curvature, whereas the solid food settles along the greater curvature of the fundus. In contrast to liquids, emptying of solid food is facilitated by the antrum, which propels solid food components into and through the pylorus. The antrum and pylorus function in a coordinated fashion, returning material to the proximal stomach until the size is suitable for delivery into the duodenum.

In addition to storing food, the stomach begins digestion of a meal. Starches undergo enzymatic breakdown through the activity of salivary amylase. Pepsin initiates protein digestion, though this hydrolysis is not completed in the stomach. The small intestine is primarily responsible for digestion of a meal and nutrient absorption.

Regulation of Gastric Function

Gastric function is under neural (sympathetic and parasympathetic) and hormonal (peptides or amines that interact with target cells in the stomach) control. An understanding of the roles of neural and hormonal regulation of digestion is critical to understanding gastric physiology and the resultant physiologic effects of gastric surgical procedures on digestion. We initially focus here on peptide regulation of gastric function and then describe the interactions of these peptides with neural inputs in regard to acid secretion and gastric function.

Gastric Peptides

Gastrin

Gastrin was initially discovered in 1905 and in 1964 became the first gastrointestinal (GI) peptide to be fully molecularly characterized. The vast majority of gastrin is produced by G cells located in the gastric antrum (see Table 86.1). It is synthesized as a prepropeptide and undergoes posttranslational processing to produce several biologically active gastrin peptides. The two major forms are gastrin-34 (big gastrin) and gastrin-17 (little gastrin). There are also relatively small percentages of gastrin-71, gastrin-14, and gastrin-6. Approximately 85% of antral gastrin is released as the 17–amino acid peptide, although gastrin-34 slightly predominates in plasma because its circulating half-life is 5 to 10 times longer. The pentapeptide sequence contained at the carboxy terminus of gastrin is identical to that found on another gut peptide, CCK. CCK and gastrin differ by their tyrosine sulfation sites. Gastrin initiates its biologic actions by activation of surface membrane receptors CCK1 and CCK2. These receptors are members of the G protein–coupled receptor family. The gastrin or CCK2 receptor has an equally high affinity for gastrin and CCK, whereas CCK1 receptors have a 1000-fold higher affinity for sulfated CCK analogues as compared with gastrin. CCK2 receptors are found on parietal and enterochromaffin-like (ECL) cells in the stomach. CCK1 receptors are more abundant in the pancreas and gallbladder.

The release of gastrin is regulated by multiple factors. Gastric distention, particularly in the antrum, leads to cholinergic activation, which in turn increases gastrin release. Cholinergic neurons also activate gastrin-releasing peptide (GRP, also referred to as *bombesin*), which directly stimulates the G cell to release gastrin. Bombesin also increases gastric mucosal blood flow both directly and by stimulating cyclooxygenase production of prostaglandins. The presence of amino acids in the stomach increases gastrin release both by direct stimulation of G cells and indirectly via GRP. G cells contain calcium receptors, so hypercalcemia can also stimulate gastrin release. Conversely, luminal acid inhibits the release of gastrin via somatostatin, particularly at intragastric pH of less than 3.0. Somatostatin inhibits gastrin by a paracrine mechanism, binding to the SSTR2 G protein–coupled receptor near antral G cells. In the antral location, somatostatin and gastrin release are functionally linked, and an inverse reciprocal relationship exists between these two peptides. Vasoactive intestinal peptide (VIP) also indirectly lowers gastrin levels by stimulating somatostatin release.

Gastrin is the major hormonal regulator of the gastric phase of acid secretion primarily by stimulating ECL cells to synthesize and release histamine. However, gastrin also exerts direct actions on the parietal cell to stimulate acid release. Gastrin has considerable trophic effects on both parietal cells and ECL cells. Prolonged hypergastrinemia from any cause leads to mucosal hyperplasia and an increase in the number of ECL cells. Gastrin is also the main hormonal regulator of the secretory response to protein-containing meals by stimulating pepsinogen release from chief cells. Pancreatic islet cells contain CCK2 receptors; thus, high levels of gastrin can increase insulin secretion.

The detection of hypergastrinemia may suggest a pathologic state of acid hypersecretion but most commonly is the result of treatment with agents to reduce acid secretion, such as proton pump inhibitors (PPIs) or chronic atrophic gastritis. Table 86.2 lists common causes of chronic hypergastrinemia. Hypergastrinemia that results from the administration of acid-reducing drugs is an appropriate physiologic response caused by loss of feedback inhibition of gastrin release by luminal acid. Lack of acid causes a reduction in somatostatin release, which causes increased release of gastrin from antral G cells. Hypergastrinemia can also occur in the setting of pernicious anemia or uremia or after surgical procedures such as vagotomy. In contrast, gastrin levels increase inappropriately in patients with gastrinoma (Zollinger-Ellison

TABLE 86.2 Causes of Hypergastrinemia

PPIs, Proton pump inhibitors.

syndrome [ZES]). These gastrin-secreting tumors are not located in the antrum and secrete gastrin autonomously. The trophic effect of gastrin on ECL cells can result in type II gastric neuroendocrine tumor development.

Somatostatin

Somatostatin in the GI system is produced by delta cells primarily in the stomach, duodenum, and pancreas. Posttranslational processing converts somatostatin into either a 14– or 28–amino acid peptide. The predominant molecular form in the stomach is somatostatin-14. It is produced by diffuse neuroendocrine cells located in the fundus and antrum. The principal stimulus for somatostatin release is antral acidification as well as GRP, whereas acetylcholine from vagal fibers inhibits somatostatin release. Somatostatin inhibits parietal cell acid secretion directly and also indirectly through inhibition of gastrin release from G cells and downregulation of histamine release from ECL cells. Somatostatin inhibits many other hormones in the GI system, including glucagon, insulin, motilin, secretin, CCK, and VIP.

Somatostatin receptors are G protein–coupled receptors. Binding of somatostatin with its receptors is coupled to one or more inhibitory guanine nucleotide–binding proteins. Parietal cell somatostatin receptors appear to be a single subunit of glycoproteins with equal affinity for somatostatin-14 and somatostatin-28. Somatostatin can inhibit parietal cell secretion through G protein–dependent and G protein–independent mechanisms. However, the ability of somatostatin to exert its inhibitory actions on cellular function is primarily thought to be mediated through the inhibition of adenylate cyclase, with a resultant reduction in cyclic adenosine monophosphate (cAMP) levels.

Histamine

Histamine plays a prominent role in parietal cell stimulation. Administration of H_2 receptor antagonists almost completely abolishes gastric acid secretion in response to gastrin and acetylcholine, suggesting that histamine may be a necessary intermediary of these pathways. Histamine is stored in the acidic granules of ECL cells and in resident mast cells. ECL cells are located in the oxyntic mucosa in close proximity to the parietal cell and play an essential role in parietal cell activation, possessing stimulatory and inhibitory feedback pathways. Histamine release is stimulated by gastrin, VIP, ghrelin, acetylcholine, and epinephrine through receptor-ligand interactions on ECL cells. In contrast, somatostatin inhibits gastrin-stimulated histamine release through interactions with somatostatin receptors located on the ECL cell. Other inhibitors of histamine release include peptide YY and prostaglandins.

Ghrelin

Ghrelin is a 28–amino acid peptide predominantly produced by the P/D1 endocrine cells of the oxyntic glands in the fundus and is a member of the motilin peptide family. Ghrelin appears to be under both endocrine and metabolic control, has a diurnal rhythm, and likely plays a major role in the neuroendocrine and metabolic responses to changes in nutritional status. Ghrelin also stimulates growth hormone release via the growth hormone secretagogue receptor. Ghrelin appears to be upregulated in times of negative energy balance and downregulated in times of positive energy balance, with high ghrelin levels during fasting and decreased levels after meals. Carbohydrates have the greatest suppressive effect on ghrelin release. Decreased ghrelin levels are associated with gastritis. Within the stomach, ghrelin increases gastric emptying and motility and increases gastric acid secretion.

In human volunteers, peripheral ghrelin administration enhances appetite and increases food intake. In patients who have undergone a gastric bypass or sleeve gastrectomy, ghrelin levels are lower.[2] Although the mechanism responsible for suppression of ghrelin levels after bariatric surgery is unknown, it is suggested that ghrelin may be responsive to the normal flow of nutrients across the stomach. Other studies have suggested that ghrelin leads to a switch toward glycolysis and away from fatty acid oxidation, which would favor fat deposition. Prader-Willi syndrome is the most common syndromic form of obesity, and these patients have been shown to have high circulating ghrelin levels that do not appropriately decrease after meals. Ghrelin antagonists may come to have a role in the treatment and prevention of obesity.

Gastric Acid Secretion

The hydrogen-potassium-ATPase (H^+/K^+-ATPase) acid–secreting pump is located in the parietal cell. Gastric acid secretion by the parietal cell is positively regulated mainly by three stimuli—acetylcholine, gastrin, and histamine. Acetylcholine is the principal neurotransmitter modulating acid secretion and is released from the vagus and parasympathetic ganglion cells; it mainly exerts effects on M3 receptors. Vagal fibers not only have a direct effect on parietal cells but also modulate peptide release from G cells and ECL cells as well as inhibit somatostatin secretion. Gastrin has direct hormonal effects on the parietal cell and also stimulates histamine release. Histamine has paracrine-like effects on the parietal cell and, as shown in Fig. 86.4, plays a central role in the regulation of acid secretion by the parietal cell after its release from ECL cells. Somatostatin exerts inhibitory actions on gastric acid secretion. Release of somatostatin from antral D cells is stimulated in the presence of low intraluminal pH as well as VIP and gastrin. After its release, somatostatin inhibits gastrin release through paracrine effects and modifies histamine release from ECL cells. Glucagon-like peptide 1 and peptide YY also inhibit gastric acid secretion. Consequently, the precise state of acid secretion by the parietal cell depends on the overall influence of the positive and negative stimuli.

Stimulated Acid Secretion

There is always a basal level of acid secretion that is approximately 2 mEq per hour. Ingestion of food is the physiologic stimulus for increasing acid secretion, with average maximal acid output of 30 mEq per hour. There are three interrelated phases of the acid secretory response to a meal: cephalic, gastric, and intestinal.

Cephalic phase. The cephalic phase originates with the sight, smell, thought, or taste of food. Although the exact mechanisms whereby these senses lead to increased acid secretion are not yet

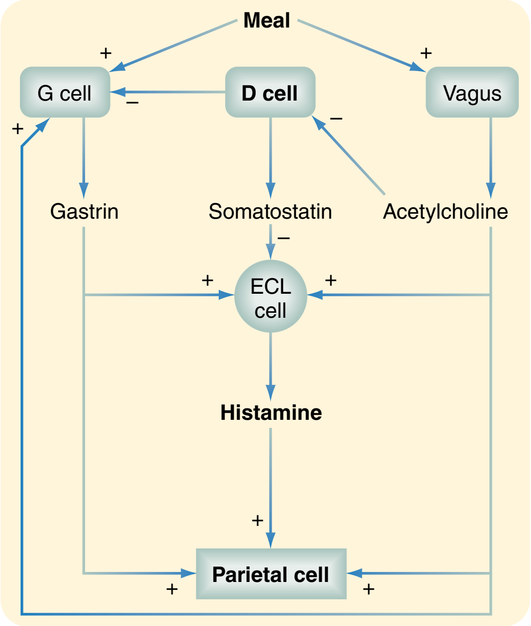

FIGURE 86.4 Central role of the enterochromaffin-like *(ECL)* cell in regulation of acid secretion by the parietal cell. As shown, ingestion of a meal stimulates vagal fibers to release acetylcholine (cephalic phase). Binding of acetylcholine to M3 receptors located on the ECL cell, parietal cell, and G cell results in the release of histamine, hydrochloric acid, and gastrin. Binding of acetylcholine to M3 receptors on D cells results in the inhibition of somatostatin release. After a meal, G cells are also stimulated to release gastrin, which interacts with receptors located on ECL cells and parietal cells to cause the release of histamine and hydrochloric acid (gastric phase). Release of somatostatin from D cells decreases histamine release and gastrin release from ECL cells and G cells. In addition, somatostatin inhibits parietal cell acid secretion (not shown). The principal stimulus for the activation of D cells is antral luminal acidification (not shown). (From Yeo C, Dempsey DT, Klein AS, et al., eds. *Shackelford's Surgery of the Alimentary Tract.* 6th ed. Philadelphia: Saunders; 2007.)

fully elucidated, it is hypothesized that several sites are stimulated in the brain, including neural centers in the hypothalamus. These higher centers transmit signals to the stomach via the vagus nerves, which release acetylcholine that activates muscarinic receptors located on target cells. Acetylcholine directly increases acid secretion by the parietal cells, stimulates ECL and G cells to release histamine and gastrin, respectively, and inhibits D cells from releasing somatostatin. Although the intensity of the acid secretory response in the cephalic phase surpasses that of the other phases, it accounts for only 20% to 30% of the total volume of gastric acid produced in response to a meal because of its short duration.

Gastric phase. The gastric phase of acid secretion begins when food enters the gastric lumen. Protein products of ingested food interact with microvilli of antral G cells to stimulate gastrin release. Food also stimulates acid secretion by causing mechanical distention of the stomach. Gastric distention as food enters the stomach, termed *receptive relaxation,* activates stretch receptors in the stomach to elicit the vagovagal reflex arc as well as local enteric nervous system acetylcholine release. The vasovagal reflex is abolished by proximal gastric vagotomy and is, at least in part, independent of changes in serum gastrin levels. Antral distention also causes gastrin release. The entire gastric phase accounts for most (60%–70%) of meal-stimulated acid output.

Intestinal phase. The intestinal phase of gastric secretion is initiated by entry of chyme into the duodenum, which initially stimulates gastrin release and suppresses gastric motility. It occurs after gastric emptying and lasts as long as partially digested food components remain in the proximal small bowel. It accounts for only 5% to 10% of the acid secretory response to a meal and does not appear to be mediated by serum gastrin levels. Chyme also stimulates release of CCK and secretin in the duodenum.

Activation and Secretion by the Parietal Cell

The two second messengers principally involved in stimulation of acid secretion by parietal cells are intracellular cAMP and calcium. These two messengers activate protein kinases and phosphorylation cascades. The intracellular events following ligand binding to receptors on the parietal cell are shown in Fig. 86.5. Histamine causes an increase in intracellular cAMP, which initiates a cascade of phosphorylation events that culminates in activation of the gastric proton pump (H^+/K^+-ATPase). In contrast, acetylcholine and gastrin stimulate phospholipase C, which converts membrane-bound phospholipids into inositol triphosphate to mobilize calcium from intracellular stores. Increased intracellular calcium activates other protein kinases that ultimately activate H^+/K^+-ATPase in a similar fashion to initiate the secretion of hydrochloric acid.

The H^+/K^+-ATPase is the final common pathway for gastric acid secretion by the parietal cell. It is a heterodimer composed of a catalytic α-subunit and a glycoprotein β-subunit. During the resting state, gastric parietal cells store H^+/K^+-ATPase intracellularly. Cellular relocation of the proton pump subunits through cytoskeletal rearrangements must occur for acid secretion to increase in response to stimulatory factors. The subsequent heterodimer assembly of the H^+/K^+-ATPase subunits and insertion into the microvilli of the secretory canaliculus allows an increase in gastric acid secretion. A KCl efflux pathway must exist to supply potassium to the extracytoplasmic side of the pump. Cytosolic hydrogen is secreted by H^+/K^+-ATPase in exchange for extracytoplasmic potassium (see Fig. 86.5), which is an electroneutral exchange and does not contribute to the transmembrane potential difference across the parietal cell. Secretion of chloride is accomplished through a chloride channel moving chloride from the parietal cell cytoplasm into the gastric lumen. The exchange of hydrogen for potassium requires energy in the form of adenosine triphosphate (ATP) because hydrogen is being secreted against a gradient of more than a millionfold. Because of this large energy requirement, the parietal cell has a mitochondrial compartment representing about one-third of its cellular volume. In contrast to stimulated acid secretion, cessation of acid secretion requires endocytosis of H^+/K^+-ATPase with regeneration of cytoplasmic tubulovesicles containing the subunits; this occurs through a tyrosine-based signal. The tyrosine-containing sequence is located on the cytoplasmic tail of the β-subunit.

Roughly 1 billion parietal cells are found in the normal human stomach and are responsible for secreting, on average, a maximum of 30 mEq per hour of hydrochloric acid in response to a meal. There is a linear relationship between maximal acid output and parietal cell number. Gastric acid secretory rates may be altered in patients with upper GI disease. For example, gastric acid is decreased in patients with pernicious anemia or atrophic gastritis. Gastric acid plays a critical role in the digestion of a meal. It is required to convert pepsinogen into pepsin, elicits the release of secretin from the duodenum, and limits colonization of the upper GI tract with bacteria.

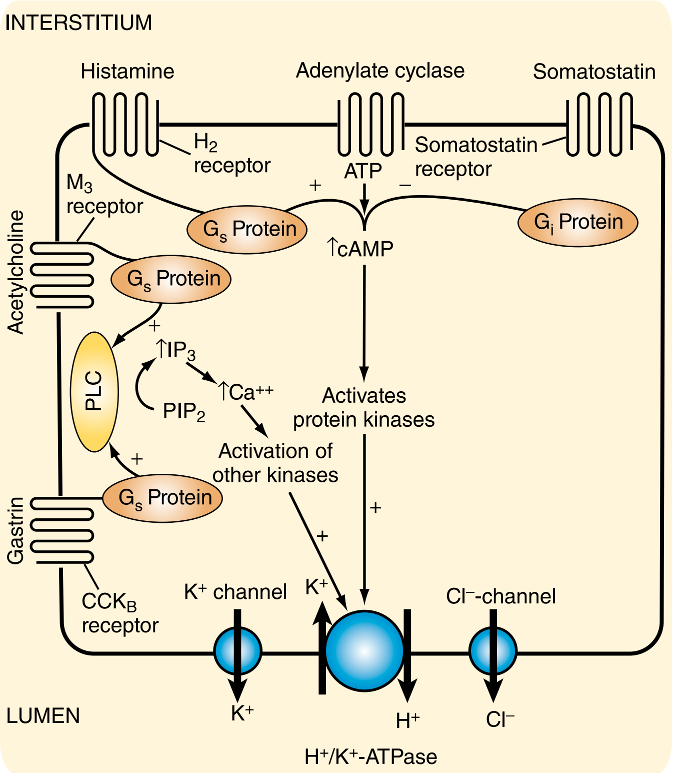

FIGURE 86.5 Intracellular signaling events in a parietal cell. As shown, histamine binds to H_2 receptors, stimulating adenylate cyclase through a G protein–linked mechanism. Adenylate cyclase activation causes an increase in intracellular cyclic adenosine monophosphate *(cAMP)* levels, which activates protein kinases. Activated protein kinases stimulate a phosphorylation cascade, with a resultant increase in levels of phosphoproteins that activate the proton pump. Activation of the proton pump leads to extrusion of cytosolic hydrogen in exchange for extracytoplasmic potassium. In addition, chloride is secreted through a chloride channel located on the luminal side of the membrane. Gastrin binds to type B cholecystokinin receptors, and acetylcholine binds to M3 receptors. After the interaction of gastrin and acetylcholine with their receptors, phospholipase C is stimulated through a G protein–linked mechanism to convert membrane-bound phospholipids into inositol triphosphate *(IP_3)*. IP_3 stimulates the release of calcium from intracellular calcium stores, leading to an increase in intracellular calcium that activates protein kinases, which activate the H^+/K^+-ATPase. *ATP,* Adenosine triphosphate; *ATPase,* adenosine triphosphatase; *G_i,* inhibitory guanine nucleotide protein; *G_s,* stimulatory guanine nucleotide protein; *PIP_2,* phosphatidylinositol 4,5-diphosphate; *PLC,* phospholipase C. (From Yeo C, Dempsey DT, Klein AS, et al., eds. *Shackelford's Surgery of the Alimentary Tract.* 6th ed. Philadelphia: Saunders; 2007.)

Other Gastric Secretory Products

Gastric juice. Gastric juice is the combined result of secretion by the parietal cells, chief cells, and mucous cells, in addition to swallowed saliva and duodenal refluxate. The two main components of gastric juice are hydrochloric acid and pepsin. The electrolyte composition varies with the rate of gastric secretion. Parietal cells secrete an electrolyte solution that is isotonic with plasma, with a pH of 0.8. The lowest intraluminal pH commonly measured in the stomach is approximately 2.0 because of dilution of the parietal cell secretion by other gastric secretions containing sodium, potassium, and bicarbonate. The acidity of gastric juice inactivates most ingested microorganisms.

Intrinsic factor. Intrinsic factor is a glycoprotein produced by the parietal cells that is essential for the absorption of vitamin B_{12} (cobalamin) in the terminal ileum. In general, secretion of intrinsic factor parallels gastric acid secretion, yet the secretory response is not linked to acid secretion. For example, PPIs do not block intrinsic factor secretion or alter the absorption of vitamin B_{12}. Intrinsic factor deficiency can develop in patients with pernicious anemia or in patients undergoing total gastrectomy. Pernicious anemia is most commonly the result of autoimmune disease targeting the parietal cells or intrinsic factor itself. Treatment typically consists of vitamin B_{12} supplementation via intramuscular injection of either cyanocobalamin or hydroxocobalamin. Large oral doses can also be used.

Pepsin. Pepsinogens are proteolytic proenzymes that are secreted by the glands of the gastroduodenal mucosa. There are five groups of pepsinogens; the two predominant types in human adults are pepsinogen A and pepsinogen C. In the stomach, pepsinogen is secreted by gastric chief cells, which are activated by gastrin and vagal nerve stimuli. In the presence of hydrochloric acid secreted by parietal cells, both forms of pepsinogen are converted to pepsin by cleavage. Pepsin is an endopeptidase that preferentially hydrolyzes peptide linkages where one of the amino acids is aromatic and accounts for approximately 20% of the protein digestion in the GI tract. Pepsins have optimal function at a pH of 1.5 to 2.0 and become inactive at a pH of 6.5, with irreversible inactivation above a pH of 8.0.

Mucus and bicarbonate. Mucus and bicarbonate combine to neutralize gastric acid at the gastric mucosal surface. They are secreted by the surface mucous cells and mucous neck cells in the antrum. Gastric mucin is a large glycoprotein; the mucus is a viscoelastic gel containing approximately 85% water and 15% mucin. It provides a mechanical barrier to injury, is relatively impermeable to pepsins, and also acts as an impediment to ion movement from the gastric lumen to the apical cell membrane. Stability of the mucin layer is largely the result of disulfide bonds. Mucus is in a constant state of flux because it is secreted continuously by mucosal cells while simultaneously being solubilized by luminal pepsin in the stomach. Mucus production is increased by vagal stimulation, cholinergic agonists, prostaglandins, and some bacterial toxins. In contrast, anticholinergic drugs and nonsteroidal antiinflammatory drugs (NSAIDs) inhibit mucus secretion. *Helicobacter pylori* secretes various proteases and lipases that break down mucin and impair the protective function of the mucus layer.

In the acid-secreting portion of the stomach, bicarbonate secretion is an active process, whereas in the antrum, active and passive secretion of bicarbonate occurs. However, the magnitude of bicarbonate secretion is considerably less than acid secretion. Although the luminal pH is 2, the pH observed at the surface epithelial cell level is usually 7. The pH gradient found at the epithelial surface is a result of the unstirred layer of water in the mucus gel and of the continuous secretion of bicarbonate by the surface epithelial cells.

Gastric Barrier Function

The stomach's barrier function depends on multiple physiologic and anatomic factors. Prostaglandins have several mucosal protection mechanisms including increasing mucosal blood flow and stimulating mucus, bicarbonate, and phospholipid secretion. Cyclooxygenase is the enzyme responsible for prostaglandin production. Thus, cyclooxygenase inhibitors such as NSAIDs and aspirin can result in gastric injury. Blood flow plays a critical role in gastric mucosal defense by providing nutrients and delivering oxygen to ensure that the intracellular processes that underlie mucosal resistance to injury can proceed unabated. Marked decreases in gastric blood flow can result in mucosal injury and ulcer formation, which is exacerbated in the presence of luminal acid. After damage occurs, injured surface epithelial cells are replaced rapidly by the migration of surface mucous cells located along the basement membranes. This process is referred to as *restitution* or *reconstitution*.

Exposure of the stomach to noxious agents causes a reduction in the potential difference across the gastric mucosa. In normal gastric mucosa, the potential difference across the mucosa is -30 to -50 mV and results from the active transport of chloride into the lumen and sodium into the blood by the activity of Na^+/K^+-ATPase. Disruption of the tight junctions between mucosal cells causes the epithelium to become leaky to ions (i.e., Na^+ and Cl^-) and a resultant loss of the high transepithelial electrical resistance normally found in gastric mucosa.

GASTRIC MOTILITY

Gastric motility is regulated on three main levels: extrinsic neural control, intrinsic neural control, and myogenic control. The extrinsic neural controls are mediated through parasympathetic (vagal) and sympathetic (splanchnic) pathways, whereas the intrinsic controls involve the enteric nervous system and interstitial cells of Cajal. Myogenic control resides in the excitatory membranes of the gastric smooth muscle cells.

Fasting Gastric Motility

The electrical basis of gastric motility begins with the depolarization of pacemaker cells located in the mid-body of the stomach along the greater curvature. Once initiated by the interstitial cells of Cajal, slow waves travel at three cycles per minute in a circumferential and antegrade fashion toward the pylorus. In addition to these slow waves, gastric smooth muscle cells are capable of producing action potentials, which are associated with larger changes in membrane potential than slow waves. During fasting, the stomach goes through a cyclical pattern of electrical activity composed of slow waves and electrical spikes, which has been termed the *migrating myoelectric complex (MMC).* Motilin, released from the small intestine, is a key stimulant of MMC initiation. Each cycle of the MCC lasts 90 to 120 minutes and consists of four distinct phases. The MMC results in clearance of gastric contents during periods of fasting. The exact regulatory mechanisms of MCC activities are unknown, but these activities remain intact after vagal denervation.

Postprandial Gastric Motility

Ingestion of a meal results in an active decrease in the resting tone of the proximal stomach and fundus, termed *receptive relaxation;* this allows for gastric accommodation of the meal with minimal increase in luminal pressure. This reflex is mediated by the vagus nerve. Thus, interruption of vagal innervation to the proximal stomach via truncal vagotomy impairs receptive relaxation, with resultant early satiety and rapid emptying of ingested liquids. In addition to its storage function, the stomach is responsible for the mechanical mixing of ingested solid food particles. This activity involves repetitive forceful contractions of the mid-body and antral portions of the stomach, causing food particles to be propelled against a closed pylorus, with subsequent retropulsion of solids and liquids. The net effect is a thorough mixing of solids and liquids and sequential shearing of solid food particles to smaller than 1 mm before passage through the pylorus to the proximal duodenum.

The emptying of gastric contents is influenced by coordinated neural and hormonal mediators. Additionally, the chemical and mechanical properties and temperature of the intraluminal contents can influence the rate of gastric emptying. In general, liquids empty more rapidly than solids, and carbohydrates empty more readily than fats. Cold liquids tend to empty at a slower rate than those at ambient temperature. These responses to luminal stimuli are regulated by the enteric nervous system. CCK, stimulated by protein and fat in the small intestine, inhibits gastric emptying. Osmoreceptors and pH-sensitive receptors in the proximal small bowel have also been shown to be involved in the activation of feedback inhibition of gastric emptying.

Abnormal Gastric Motility

Gastroparesis is the combination of objectively delayed gastric emptying and resultant symptoms in the absence of mechanical obstruction.[3] Symptoms of gastroparesis are nausea/vomiting, early satiety, abdominal pain, and bloating. In the most severe cases, patients can suffer weight loss. The first steps in evaluating patients with suspected abnormal gastric motility after history and physical examination should be to exclude a mechanical obstruction with upper endoscopy and either a computed tomographic (CT), magnetic resonance (MR) enterography, or barium follow-through. The most common causes of gastroparesis are idiopathic, diabetes mellitus, viral infection (i.e., cytomegalovirus [CMV] and Epstein-Barr virus [EBV]), neurologic disease (i.e., multiple sclerosis, stroke, Parkinson disease), autoimmune disease, and certain medications such as narcotics, tricyclic antidepressants, calcium channel blockers, and cyclosporine. Additionally, gastric motility can be impaired after surgery because of either intentional or accidental vagotomy. Vagotomy results in loss of receptive relaxation and gastric accommodation in response to meal ingestion, with resultant early satiety, postprandial bloating, accelerated emptying of liquids, and delay in emptying of solids.

Clinical manifestations of diabetic gastropathy, which can occur in insulin-dependent or non–insulin-dependent patients, are thought to be related to a variety of factors. Up to 50% of patients with diabetes have objective delayed gastric emptying; however, many have no or minimal symptoms. Impaired neural control via the vagus nerve, myenteric nervous system, interstitial cells of Cajal, oxidative stress, and the underlying smooth muscle have been implicated. Additionally, hyperglycemia itself has been shown to cause a decrease in contractility of the gastric antrum and an increase in pyloric contractility, to relax the proximal stomach, and to suppress the MMC. Hyperinsulinemia, which is often associated with non–insulin-dependent diabetes, may play a role in the gastroparesis seen in this condition because it also leads to suppression of MMC activity.

Gastric-Emptying Studies

There are numerous ways to assess gastric emptying. The most commonly used is nuclear scintigraphy. Scans are obtained immediately after ingestion of a technetium-labeled meal and at 1, 2, and 4 hours after the meal. Standard upper normal limits for gastric retention are 90% at 1 hour, 60% at 2 hours, and 10% at 4 hours. The measurement of residual gastric contents at 4 hours is the most sensitive for diagnosing gastroparesis. At 4 hours, retention of 10% to 15% signifies mild gastroparesis, 15% to 35% is moderate, and greater than 35% is severe. There are multiple other diagnostic options; however, they are used less frequently. An upper abdominal x-ray series after barium swallow can provide information on gastric emptying and may reveal mechanical causes that could contribute to a delay, such as gastric outlet obstruction. Wireless motility capsules have also been investigated as an alternative to scintigraphy, which can measure the pH, temperature, and pressure amplitude during their transit through the GI tract. Noninvasive breath tests, such as ^{13}C-spirulina, measure the expiratory $^{13}CO_2$ concentration after an isotope-labeled meal. Antropyloroduodenal manometry can reveal excessive tonic pressure at the pylorus, and newer technology such as endoluminal functional lumen imaging probes can measure the pyloric dimensions, possibly identifying patients who would benefit from pyloric interventions. An electrogastrogram or autonomic testing can aid in identifying the underlying etiology of gastroparesis, though the resulting clinical implications are unclear at this time.

Treatment

Regardless of the cause of gastroparesis, initial first-line treatment of mild gastroparesis involves dietary modification.[4] Patients should be encouraged to eat multiple small meals low in fat and insoluble fiber. Acidic and spicy foods should also be avoided. In patients who cannot tolerate solid foods, a liquid diet can be used. Attention to hydration, vitamin deficiency, and electrolyte abnormalities is necessary in patients with recurrent vomiting. Medications that affect gastric motility, such as opioids, calcium channel blockers, tricyclic antidepressants, and dopamine agonists, should be stopped when possible. Glycemic control should be optimized in patients with diabetes.

Pharmacologic therapy is necessary for persistent symptoms despite conservative measures. First-line medical therapy is metoclopramide, a dopamine D2 receptor antagonist that stimulates antral contractions and decreases postprandial relaxation of the fundus. Metoclopramide also has central nervous system antinausea effects and is the only FDA-approved medication for gastroparesis. Outside of the United States, domperidone, another D2 antagonist, is an available option. Macrolide antibiotics (erythromycin and azithromycin) are motilin agonists that act by stimulating fundal contraction and have also shown benefit. However, their prokinetic effects are limited by tachyphylaxis and thus can be considered for second-line therapy. Other prokinetic agents (5-HT4 and ghrelin receptor agonists) can be considered in refractory cases. Antinausea medications should be prescribed for symptom management.

Endoscopic or surgical management can be considered in patients with refractory symptoms despite maximal medical therapy. Venting gastrostomy tubes can alleviate symptoms, and jejunostomy tubes can provide nutritional support for patients with severe gastroparesis. A trial of nasogastric (NG) decompression and nasojejunal feeding should be performed before either procedure. Gastrostomy and jejunostomy tubes are typically able to be placed endoscopically, though surgical placement is also possible. Enteral nutrition is preferred to parenteral nutrition for long-term management of severe gastroparesis when possible.

Gastric electric stimulation is currently approved as a humanitarian exemption use device by the FDA for refractory idiopathic and diabetic gastroparesis. Permanent stimulators are implanted surgically via either an open or laparoscopic approach. Two electrical leads are placed in the muscularis propria of the greater curvature approximately 10 cm proximal to the pylorus and connected to a subcutaneously positioned simulator that delivers high-frequency, low-energy current. Symptoms of nausea, vomiting, and pain are reported to improve in observational studies; however, these effects are much less in small blinded randomized trials. Pyloromyotomy and pyloroplasty are options for the surgical management of gastroparesis that function by lowering outflow resistance at the pylorus and enhancing any remaining gastric contractility. Measurements of pyloric function described earlier can be used to guide patient selection for these interventions. A systematic review of 38 studies reported that pyloric surgery improved nausea and abdominal pain more than gastric electrical stimulation[5]; however, patient selection criteria for intervention were heterogeneous, and robust comparative trials are lacking. Gastric peroral endoscopic myotomy (G-POEM) is being increasingly used in place of surgical pyloromyotomy. A prospective randomized trial comparing G-POEM with a sham procedure in patients with severe gastroparesis was stopped early after interim analysis after 41 patients showed significant improvement in symptoms and gastric emptying at 4 hours.[6] Trials evaluating pyloric measurement before the G-POEM procedure are ongoing. Endoscopic pyloric dilation and stenting can also be considered in select settings.

PEPTIC ULCER DISEASE

Peptic ulcers are erosions in the GI mucosa that extend through the muscularis mucosae. The most common symptom of peptic ulcer disease (PUD) is dyspepsia, though the majority of patients with peptic ulcers are asymptomatic. PUD can be complicated by bleeding, gastric outlet obstruction, and perforation. The two predominant causes of PUD are *H. pylori* and NSAIDs. Many other less common mechanisms exist as well, including ZES, other medication and infectious exposures, radiation therapy, and gastric bypass surgery.

Epidemiology

The incidence and prevalence of PUD worldwide have been declining in recent decades, as has the progression to complicated PUD. Both the age-standardized incidence and prevalence of PUD from the Global Burden of Disease study decreased worldwide by 31% from 1990–2019.[7] Although PUD remains an important cause of hospitalization and morbidity, the rates of hospitalization and mortality have also decreased over time.[8] Similarly, a composite index including mortality, disability, and prevalence-to-incidence ratios showed overall improved quality of care globally over the previous decades, though heterogeneity still exists.[7] Much of this decline in ulcer incidence and the need for hospitalization has stemmed from increased knowledge of ulcer pathogenesis. Specifically, the role of *H. pylori* has been clearly defined and the risks of long-term NSAID use have been better elucidated. The need for surgery in the treatment of ulcer disease has also decreased primarily as a result of a marked decline in elective surgical therapy for chronic disease.

Pathogenesis

Peptic ulcers are caused by decreased protective factors, increased damaging factors, or both. Protective (or defensive) factors include mucosal bicarbonate secretion, mucus production, adequate mucosal blood flow, growth factors, cell renewal, and endogenous prostaglandins. Damaging or aggressive factors include hydrochloric acid secretion, pepsins, ethanol ingestion, smoking, duodenal reflux of bile, ischemia, NSAIDs, hypoxia, and, most notably, *H. pylori* infection. Although it is now clear that most ulcers are caused by *H. pylori* infection or NSAID use, it is still important to understand all of the other protective and causative factors to optimize treatment and ulcer healing and prevent disease recurrence.

Helicobacter pylori Infection

The global prevalence of *H. pylori* infection is estimated to be approximately 43%, which is decreased from 58% in the 1980s.[9] This decrease is multifactorial, with improvements in diagnosis, treatment, and environmental factors playing a role. Approximately 80% of people with *H. pylori* are asymptomatic. *H. pylori* remains the predominant risk factor for PUD, associated with 90% of duodenal ulcers and 70% to 90% of gastric ulcers.[10] Infection with *H. pylori* has been shown to temporally precede ulcer formation, and when this organism is eradicated as part of ulcer treatment, ulcer recurrence is extremely rare. These observations have secured the place of *H. pylori* as a primary causative factor in the pathogenesis of PUD.

The interplay between bacterial and host factors determines the clinical outcome of *H. pylori* infection. *H. pylori* is a spiral-shaped, flagellate, microaerophilic, gram-negative bacteria that resides in gastric-type epithelium within or beneath the mucus layer. Its shape and flagella aid its movement through the mucus layer. Mucolytic enzyme production facilitates passage through the mucus layer and protects the bacteria from mucin's antibiotic effects. *H. pylori* is a potent producer of urease, which is capable of splitting urea into ammonia and bicarbonate. This creates an alkaline microenvironment in the setting of an acidic gastric milieu, allowing for the bacteria's survival in the stomach. The bacteria attach to the gastric epithelial cells by binding to surface adhesins and are able to enter the mucus layer via flagella-driven motility.

The exact mechanisms responsible for *H. pylori*–induced GI injury are still not fully understood, but the following four potential mechanisms have been proposed (and likely interact) to cause a derangement of normal gastric and duodenal physiology that leads to subsequent ulcer formation:

1. *Production of toxic products that cause local tissue injury*. Locally produced toxic mediators include breakdown products from urease activity (e.g., ammonia), cytotoxins, mucinase (which degrades mucus and glycoproteins), phospholipases that damage both epithelial and mucus cells, and platelet-activating factor (which is known to cause mucosal injury and thrombosis in the microcirculation). *H. pylori* strains that produce both CagA (cytotoxin-associated gene A) and VacA (vacuolating cytotoxin) virulence factors induce more inflammation; CagA-positive strains are also associated with gastric adenocarcinoma.[11]
2. *Induction of a local mucosal immune response*. The lipopolysaccharides of *H. pylori* have evolved to largely be unrecognized by the human innate immune system, allowing for immune evasion and colonization. *H. pylori* can cause a local inflammatory reaction in the gastric mucosa via multiple innate immune pathways, attracting neutrophils and monocytes, which then produce numerous proinflammatory cytokines and reactive oxygen metabolites.
3. *Increased gastrin levels and changes in acid secretion*. In patients with antral *H. pylori* infection, basal and stimulated gastrin levels are significantly increased secondary to a reduction in somatostatin release from antral D cells because of infection with *H. pylori*. During the acute phase of *H. pylori* infection, acid secretion is decreased. With chronic infection, *H. pylori* has trophic effects on ECL and G cells, which can result in acid hypersecretion. The decrease in serum levels of somatostatin also contributes to the gastric hyperacidity. However, if oxyntic glands are destroyed by the chronic infection, hypoacidity will result.
4. *Gastric metaplasia occurring in the duodenum*. Metaplastic replacement of duodenal mucosa with gastric epithelium likely occurs as a protective response to decreased duodenal pH resulting from the previously described acid hypersecretion. This allows for *H. pylori* to colonize these areas of the duodenum, which causes duodenitis and likely predisposes to duodenal ulcer formation. The presence of *H. pylori* in the duodenum is more common in patients with ulcer formation compared with patients with asymptomatic infections isolated to the stomach.

Peptic ulcers are strongly associated with antral gastritis. Studies performed before the *H. pylori* era demonstrated that almost all patients with peptic ulcers have histologic evidence of antral gastritis. In most cases, the infection tends to be confined initially to the antrum and results in antral inflammation. The causative role of *H. pylori* infection in the pathogenesis of gastritis and PUD was first elucidated by Marshall and Warren in Australia in 1984.[12] Marshall himself ingested inocula of *H. pylori*, and within days he developed abdominal pain, nausea, and histologically confirmed presence of gastric *H. pylori* infection. Acute inflammation was observed histologically on days 5 and 10. By 2 weeks, acute inflammation had been replaced by chronic inflammation with evidence of a mononuclear cell infiltration. For their pioneering work, Marshall and Warren were jointly awarded the Nobel Prize in Physiology or Medicine in 2005.

Evidence of infection can be seen in early childhood. There is an inverse relationship between infection rates and socioeconomic status. The reasons for this relationship are poorly understood, but it seems to be the result of environmental factors such as sanitation, familial clustering, lack of running water, and overcrowding. Such factors likely also explain why developing countries have a comparatively higher rate of *H. pylori* infection, especially in children. *H. pylori* infection is associated with many common upper GI disorders and is almost always present in the setting of active chronic gastritis, but most infected individuals are asymptomatic. In addition, up to 90% of patients with gastric cancer have current or past *H. pylori* infection; the WHO classified *H. pylori* as a class I carcinogen in 1994. The lifetime gastric cancer risk associated with *H. pylori* infection is estimated at 1% to 5% depending on other genetic, environmental, and patient risk factors. There is also a strong association between mucosa-associated lymphoid tissue (MALT) lymphoma and *H. pylori* infection. Regression of these lymphomas has been demonstrated after eradication of *H. pylori*.[13]

Invasive Diagnostic Tests for *Helicobacter pylori*

Urease assay. Endoscopic biopsy specimens should be taken from the gastric body and the antrum and then tested for urease. Sensitivity in diagnosing infection is 84% to 95%, and specificity is 95% to 100%. However, the sensitivity of the test is lowered in patients with acute bleeding or who are taking PPIs, H_2 receptor antagonists, or antibiotics. Rapid urease test kits are commercially available and can detect urease in gastric biopsy specimens within 1 hour with a similar level of diagnostic accuracy.

Histology. Endoscopy can also be performed with biopsy samples of gastric mucosa, followed by histologic visualization of *H. pylori* using either routine hematoxylin-eosin stains or special stains (e.g., Giemsa stain). Sensitivity is approximately 95% and specificity is 99%, making histology slightly more accurate than the urease assay testing. Similar to the urease assay, the sensitivity of histologic evaluation is lower in patients taking PPIs or H_2 antagonists, but it remains the most accurate test available even in this setting. Histology additionally affords the ability to assess the severity of gastritis and confirm the presence or absence of the organism; however, it is more expensive than the rapid urease assay.

Culture. Culturing of gastric mucosa obtained at endoscopy can also be performed to diagnose *H. pylori*. The sensitivity is approximately 80%, and specificity is 100%. However, culture requires laboratory expertise, is not widely available, and is relatively expensive, and diagnosis requires 3 to 5 days. The advantage of culture is that it provides the opportunity to perform antibiotic sensitivity testing especially given increasing antibiotic resistance.

Noninvasive Diagnostic Tests for *Helicobacter pylori*

Urea breath test. The carbon-labeled urea breath test is based on the ability of *H. pylori* to hydrolyze urea as a result of its production of urease and is the most commonly used noninvasive diagnostic test. Both sensitivity and specificity are greater than 95%. As with other testing modalities, the sensitivity of the urea breath test is reduced in patients taking PPIs and antibiotics. It is recommended that patients discontinue antibiotics for 4 weeks and PPIs for 2 weeks to ensure optimal test accuracy. The urea breath test is less expensive than endoscopy and samples the entire stomach. In evaluating treatment efficacy, false-negative results can occur if the test is performed too soon after treatment, so it is usually best to perform this test 4 weeks after therapy is completed.

Stool antigen. *H. pylori* bacteria are present in the stool of infected patients, and several assays have been developed that use monoclonal antibodies to *H. pylori* antigens to test fecal specimens. These tests have demonstrated sensitivities and specificities of greater than 95%. Several studies have shown that stool antigen testing has an accuracy of greater than 90% in detecting eradication of infection after treatment, on par with invasive histology and noninvasive urea breath testing.

Serology. Various enzyme-linked immunosorbent assay laboratory-based tests are available and some rapid office-based immunoassays that are used to test for the presence of IgG antibodies to *H. pylori*. There is heterogeneity between various serologic test kits, with sensitivity ranging from 57% to 100% and specificity from 58% to 96%. Test kits need to be locally validated based on the prevalence of specific bacterial strains. Furthermore, antibody titers can remain high for 1 year or longer after eradication; consequently, this test cannot be used to distinguish between active and prior infection or to assess response to therapy. Serologic testing can be helpful if trying to assess for prevalence of disease in a location. For these reasons, stool antigen and urea breath tests are the preferred noninvasive modalities for diagnosis and evaluation of treatment efficacy in patients with PUD and suspected *H. pylori* infection.

Nonsteroidal Antiinflammatory Drugs

NSAIDs, including aspirin, are absorbed through the stomach and small intestine and function as inhibitors of the cyclooxygenase enzymes. Cyclooxygenase enzymes form the rate-limiting step of prostaglandin synthesis in the GI tract. Prostaglandins (including thromboxane A2) promote gastric and duodenal mucosal protection from luminal acid and pepsin via numerous mechanisms, including increasing mucin and bicarbonate secretion, increasing blood flow to the mucosal endothelium, and promoting epithelial cell proliferation and migration to the luminal surface. NSAIDs disrupt these naturally protective mechanisms, increasing the risk of peptic ulcer formation in the stomach and the duodenum.

The use of NSAIDs is associated with a threefold to fourfold higher risk of PUD independent of *H. pylori* status. NSAID use also increases the risk of complicated PUD (including bleeding, obstruction, and perforation). NSAID-induced ulcers are more often found in the stomach. *H. pylori* ulcers are also almost always associated with chronic active gastritis, whereas gastritis is not always seen with NSAID-induced ulcers. When NSAID use is discontinued, the ulcers usually do not recur unless there is an untreated *H. pylori* infection as well.

Gastric and Duodenal Ulcers

Gastric Ulcer Types

The modified Johnson anatomic classification system for gastric ulcers (types I–V, described in Table 86.3) was developed before the modern understanding that most ulcers are the consequence of *H. pylori* infection or NSAID usage. However, despite having an increased understanding of the mechanisms of how and why most ulcers develop, this historical classification system is still relevant to surgical treatment because it dictates what operation should be performed.

Gastric ulcers can occur at any location in the stomach, although they usually manifest on the lesser curvature near the incisura. Approximately 50% to 60% of gastric ulcers are in this location and are classified as type I gastric ulcers. These ulcers occur with low to normal gastric acid output. Most occur near the histologic transition zone between the fundic and antral mucosa. Type II gastric ulcers (accounting for approximately 15%–20%) are located in the body of the stomach in combination with a duodenal ulcer. Type II ulcers are associated with excess acid secretion. Type III gastric ulcers are prepyloric ulcers and account for approximately 20% of the lesions. They behave similar to duodenal ulcers and are associated with hypersecretion of gastric acid. Type IV gastric ulcers occur high on the lesser curvature near the GE junction. The incidence of type IV gastric ulcers is less than 10%, and they are not associated with excessive acid secretion. Type V gastric ulcers can occur at any location and are associated with long-term NSAID use.

Gastric ulcers rarely develop before the age of 40 years, and the peak incidence occurs in individuals 55 to 65 years old. Some risk factors that may predispose to gastric ulceration include chronic alcohol intake, smoking, radiation therapy, and long-term corticosteroid therapy. The presence of acid appears to be essential to the production of a gastric ulcer; however, the total secretory output appears to be less important. In contrast to the acidification of the duodenum leading to ulcer formation, patients with gastric ulcers caused by *H. pylori* can have normal or reduced total gastric acid production. Gastric ulcer formation is more likely caused by an inflammatory response to the bacterial infection itself.

TABLE 86.3 Gastric Ulcer Types

TYPE	LOCATION	ACID LEVEL
I	Lesser curve at incisura	Low to normal
II	Gastric body with duodenal ulcer	Increased
III	Prepyloric	Increased
IV	High on lesser curve	Normal
V	Anywhere	Normal, NSAID-induced

NSAID, Nonsteroidal antiinflammatory drug.

Gastric Ulcer Clinical Manifestations

One clinical challenge of gastric ulcer management is the differentiation between gastric carcinoma and a benign ulcer. This is in contrast to duodenal ulcers, in which malignancy is extremely rare. Similar to duodenal ulcers, gastric ulcers are also characterized by recurrent episodes of epigastric pain. Complications of gastric ulcer disease include bleeding, obstruction, and perforation. Occasionally, benign ulcers have also been found to result in spontaneous gastrocolic fistulas. Surgical intervention is required in patients who develop complications from gastric ulcer disease. The most frequent complication overall of gastric ulceration is bleeding, with the most common requiring surgery being perforation. Most perforations occur along the anterior aspect of the lesser curvature. Gastric outlet obstruction can also occur in patients with type II or III gastric ulcers. However, one must carefully differentiate between benign obstruction and obstruction secondary to carcinoma.

Duodenal Ulcer: Clinical Manifestations

Patients with duodenal ulcer disease can present in various ways. The most common symptom associated with duodenal ulcer disease is midepigastric abdominal pain that is usually well localized. The pain is generally tolerable and frequently relieved by food. When the pain becomes constant, this suggests that there is deeper penetration of the ulcer. Referral of pain to the back is usually a sign of penetration into the pancreas, whereas diffuse peritoneal irritation is the result of free perforation.

Diagnosis and Management of Gastric and Duodenal Ulcers

The diagnosis and treatment of gastric ulceration generally mirror that of duodenal ulcer disease. The significant difference is the possibility of malignancy in a gastric ulcer. This critical difference necessitates that cancer be ruled out in acute and chronic presentations of gastric ulcer disease. Acid suppression and *H. pylori* eradication are important aspects of any treatment and are further detailed next.

Intractable nonhealing ulcers are becoming increasingly less common with improvements in medical therapy. It is important to ensure that adequate time has elapsed and appropriate therapy has been administered to allow healing of the ulcer to occur; this includes confirmation that *H. pylori* has been eradicated and that NSAIDs have been eliminated. The presentation of a nonhealing gastric ulcer in the *H. pylori* era should raise serious concerns about the presence of an underlying malignancy. These patients should undergo a thorough evaluation with multiple biopsies to exclude malignancy (Fig. 86.6). The approach for a complicated gastric ulcer varies depending on the type of ulcer and its association with pathophysiologic acid levels. Type I and IV ulcers, which are not associated with increased acid levels, do not require acid-reducing vagotomy. Fig. 86.7 is an algorithm for surgical management of complicated gastric ulcers.

History and physical examination are of limited value in distinguishing between gastric and duodenal ulceration. Routine laboratory studies include complete blood count, liver chemistries, serum creatinine, serum amylase, and calcium levels. A serum gastrin level should also be obtained in patients with ulcers that are refractory to medical therapy or require surgery. The two principal means of diagnosing gastric and duodenal ulcers are upper GI radiography and flexible upper endoscopy.

Upper gastrointestinal radiography. Diagnosis of gastric or duodenal ulcer by upper GI radiography requires the demonstration of barium within the ulcer crater, which is usually round or

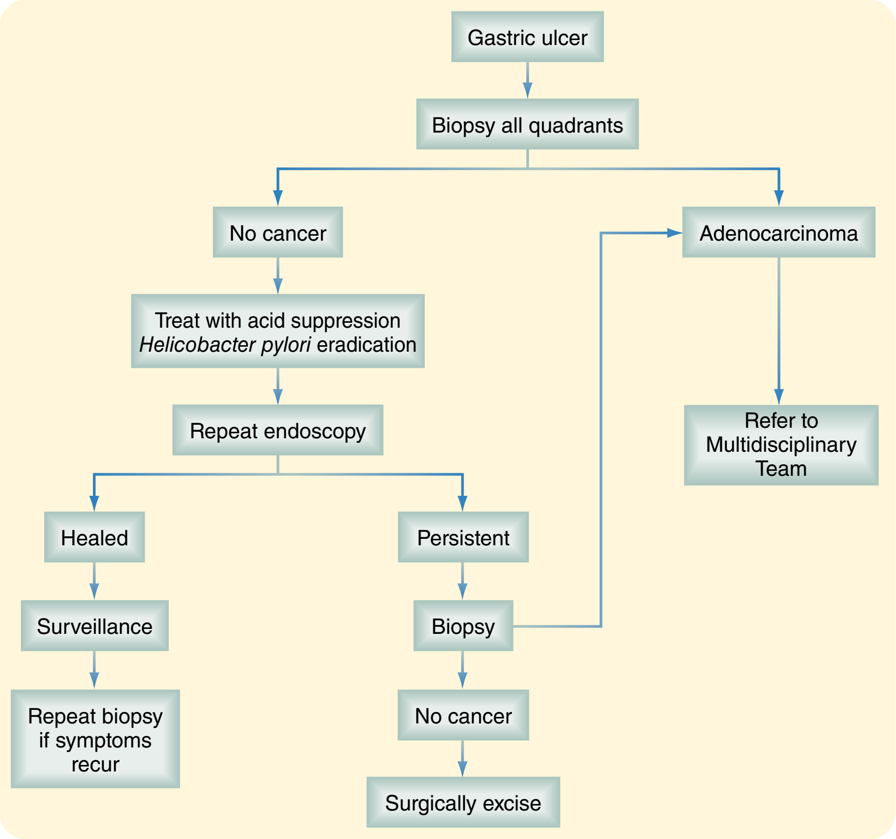

FIGURE 86.6 Algorithm for evaluation, treatment, and surveillance of a patient with a gastric ulcer.

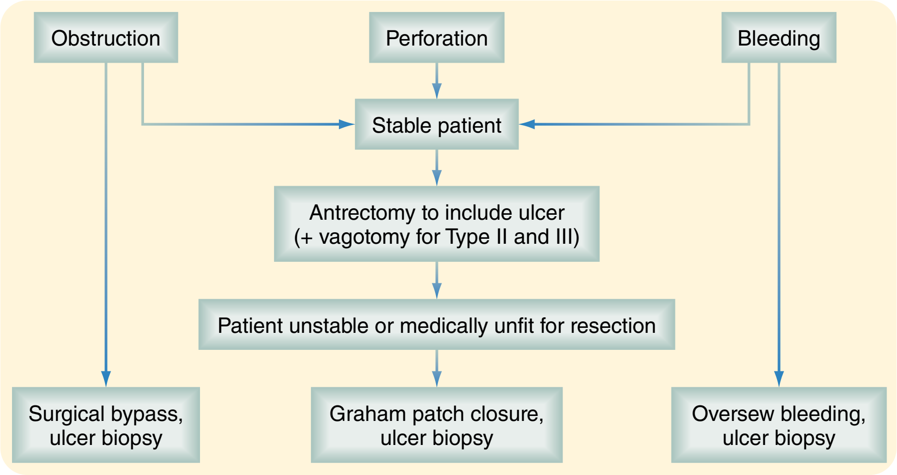

FIGURE 86.7 Algorithm for the surgical management of complicated gastric ulcer disease.

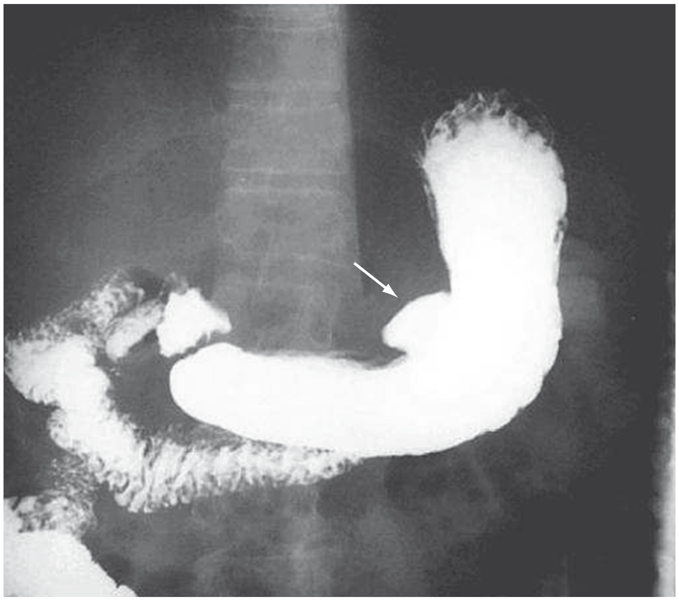

FIGURE 86.8 A large, benign-appearing gastric ulcer protrudes medially from the lesser curvature of the stomach *(arrow)*, just above the gastric incisura. (Courtesy Dr. Agnes Guthrie, Department of Radiology, University of Texas Medical School, Houston, TX.)

oval. The ulcer may be surrounded by edema. This study is useful to determine the location and depth of penetration of the ulcer and the extent of deformation from chronic fibrosis. A characteristic barium radiograph of a peptic ulcer is shown in Fig. 86.8. The ability to detect ulcers on radiography requires the technical skills and abilities of the radiologist but also depends on the size and location of the ulcer. With single-contrast radiographic techniques, 50% of ulcers may be missed, whereas with double-contrast studies, 80% to 90% of ulcer craters can be detected. However, upper GI radiography has largely been replaced by flexible upper endoscopy as the diagnostic method of choice for both gastric and duodenal ulcers.

Flexible upper endoscopy. Endoscopy is the most reliable method for diagnosing gastric and duodenal ulcers. In addition to providing a visual diagnosis, endoscopy provides the ability to sample tissue to evaluate for malignancy and *H. pylori* infection and may be used for therapeutic purposes in the setting of GI bleeding or obstruction. Endoscopy also can evaluate for other pathologies of the esophagus, stomach, and duodenum that may be causing the patient's symptoms.

When a gastric ulcer has been detected endoscopically, biopsy is generally recommended in all cases to rule out malignancy. In very low-risk patients with benign-appearing ulcers, foregoing biopsy can be considered.[14] Larger ulcers and ulcers with irregular or heaped-up edges are more likely to harbor cancers. Multiple biopsy specimens should be taken of the ulcer for maximum diagnostic yield, preferably from all four quadrants if possible. An early study of the usefulness of endoscopic biopsy showed that the first biopsy sample taken of an ulcer had only a 70% sensitivity in detecting gastric cancer, whereas taking four biopsy specimens increased this yield to 95%, and taking seven specimens increased it further to 98%.[15]

Medical Treatment

Antiulcer drugs fall into three broad categories—drugs that reduce acid levels by decreasing secretion or chemical neutralization, drugs targeted against *H. pylori,* and drugs that increase the mucosal protective barrier. In patients with PUD and *H. pylori* infection, the focus of therapy is on eradication of the bacteria. In addition to medications, lifestyle changes, such as smoking cessation, discontinuing NSAIDs and aspirin, and avoiding alcohol, help promote ulcer healing.

Proton pump inhibitors. The most potent antisecretory agents are PPIs. After oral administration, PPIs are absorbed into the bloodstream as prodrugs and selectively concentrate in the secretory canaliculus of the parietal cell. At low pH, they become ionized and activated, with the formation of an active sulfur group. The cysteine residues on the α-subunit of the H^+/K^+-ATPase form a covalent disulfide bond with activated PPIs, which irreversibly inhibits the proton pump. Because of the covalent nature of this bond, these PPIs have more prolonged inhibition of gastric acid secretion than H_2 receptor antagonists. For recovery of acid secretion to occur, new protein pumps must be synthesized. PPIs have a healing rate of 85% at 4 weeks and 96% at 8 weeks and produce more rapid healing of ulcers than H_2 receptor antagonists. Because of this, PPIs have become the primary antisecretory therapy for PUD. PPIs require an acidic environment within the gastric lumen to become activated; thus, using antacids or H_2 receptor antagonists in combination with PPIs could have deleterious effects by promoting an alkaline environment. Maintenance PPI therapy is considered in patients with large (>2 cm) ulcers, refractory or frequent PUD, those who failed *H. pylori* eradication, or patients requiring continued NSAID/aspirin use.

Histamine H_2 receptor antagonists. The histamine H_2 receptor antagonists are structurally similar to histamine and function by inhibiting the H_2 receptors on parietal cells. Currently available H_2 receptor antagonists differ in their potency but only modestly in half-life and bioavailability. Famotidine is the most potent, and cimetidine is the weakest. However, as stated earlier, PPIs are preferred. In a meta-analysis of randomized controlled trials, PPIs showed significantly improved ulcer healing and rebleeding in patients who presented with a GI bleed as compared with H_2 receptor antagonists.[16]

Treatment of* Helicobacter pylori *infection. After it became clear that the majority of cases were caused by *H. pylori* infection, there was a paradigm shift that saw PUD as an infectious disease, rather than solely a consequence of pathologic acid secretion. Accordingly, treatment philosophy has shifted to focus on eradication of the infectious agent when present.

Current therapy is twofold in its approach, combining antibiotics against *H. pylori* with acid-reducing medications. The primary goal of the acid-reducing medication is to promote short-term healing by reducing pathologic acid levels and to improve patient symptoms. *H. pylori* eradication also helps with initial healing, but its primary efficacy is in preventing recurrence. There have been numerous trials comparing eradication therapy with ulcer-healing drugs alone or no treatment. Eradication of *H. pylori* has shown recurrence rates of 2%, with initial healing rates of 90%. However, eradication rates after an initial course of therapy have been decreasing, likely as a result of increased prevalence of antibiotic-resistant strains of *H. pylori;* approximately 20% to 30% of patients fail initial therapy. For this reason, monitoring for infection eradication with a urea breath test, stool antigen, or repeat endoscopy with biopsy at 4 to 6 weeks after therapy is important, as many patients will require further treatment with alternative regimens.

The treatment of *H. pylori*–positive PUD is triple or quadruple therapy aimed at the eradication of *H. pylori* (Box 86.1). This triple therapy includes a PPI and two antibiotics, with the addition of bismuth representing quadruple therapy. The choice of antibiotics should be guided by risk factors for macrolide resistance and presence of a penicillin allergy. When available, regional antibiotic susceptibility data should also help guide initial treatment regimen choice. Risk factors for macrolide resistance are prior exposure to a macrolide antibiotic or local clarithromycin resistance rates of greater than 15%. Patients who do not have risk factors for macrolide resistance and are not allergic to penicillin should receive standard triple therapy, consisting of clarithromycin, amoxicillin, and a PPI. The amoxicillin can be replaced with metronidazole if the patient has a penicillin allergy. Patients who have a risk factor for macrolide resistance should be given bismuth quadruple therapy, which consists of bismuth, tetracycline, metronidazole, and a PPI. Bismuth quadruple therapy should also be given to patients with a penicillin allergy and recent metronidazole use.

Clinical guidelines generally recommend treatment with a 14-day course of triple therapy and a 10- to 14-day course of bismuth quadruple therapy.[17] Side effects include diarrhea, nausea/vomiting, rash, and altered taste. The side effects are generally mild and resolve with cessation of treatment. Resistance to antibiotics is increasing and varies geographically. In a systematic review and meta-analysis from 2018, worldwide rates of clarithromycin resistance ranged from 20% to 35%, metronidazole from 29% to 60%, and levofloxacin from 12% to 31%.[18] For the 20% to 30% of patients with refractory disease, a treatment course with new antibiotics, such as metronidazole and tetracycline, is initiated, and quadruple therapy with the addition of bismuth is recommended if not previously used. Levofloxacin and rifabutin triple therapies represent other salvage therapeutic options.[19]

BOX 86.1 First-Line *Helicobacter pylori* Treatment Regimen

Patients without penicillin allergy, prior macrolide exposure, or in a region with >5% clarithromycin resistance:

- Clarithromycin triple therapy (PPI, clarithromycin, and amoxicillin)
- Bismuth quadruple therapy (PPI, bismuth, tetracycline, metronidazole)
- Concomitant regimen (PPI, clarithromycin, amoxicillin, nitroimidazole)

Patients without penicillin allergy with either prior macrolide exposure or in a region with >15% clarithromycin resistance:

- Bismuth quadruple therapy
- Levofloxacin triple therapy (PPI, levofloxacin, amoxicillin)

Patients with a penicillin allergy but without prior macrolide exposure:

- Bismuth quadruple therapy
- Clarithromycin triple therapy with metronidazole (PPI, clarithromycin, and amoxicillin)

Patients with both a penicillin allergy and either prior macrolide exposure or in a region with >15% clarithromycin resistance:

- Bismuth quadruple therapy

PPI, Proton pump inhibitor.

Antacids. Antacids are the oldest form of therapy for PUD. They reduce gastric acidity by reacting with hydrochloric acid, forming a salt and raising the gastric pH. Antacids differ greatly in their buffering ability, absorption, and side effects. Antacids typically contain aluminum hydroxide, calcium carbonate, or magnesium trisilicate and can be used to neutralize gastric acid and decrease acid delivery to the duodenum, though the exact mechanism of action is unclear. Magnesium antacids tend to be the best buffers but can cause significant diarrhea, whereas acids precipitated with phosphorus can occasionally result in hypophosphatemia and sometimes constipation. Aluminum hydroxide can bind growth factors and may increase their delivery to injured mucosa. The use of antacids has largely been replaced by the more efficacious antisecretory therapies (either H_2 receptor antagonists or PPIs) for the treatment of PUD.

Sucralfate. Sucralfate is structurally related to heparin but does not have any anticoagulant effects. It is an aluminum salt of sulfated sucrose that dissociates under the acidic conditions in the stomach. It is hypothesized that the sucrose polymerizes and binds to the ulcer crater to produce a protective coating that can last for 6 hours. Sucralfate has also been shown to stimulate angiogenesis and granulation tissue formation. The efficacy and role of sucralfate in healing peptic ulcers caused by *H. pylori* infection has not been clearly established, and sucralfate is not currently included as part of initial treatment guidelines for PUD.

Complicated Peptic Ulcer Disease

Ulcer surgery was previously a major part of general surgery practice. With the shift in understanding the pathophysiology of

BOX 86.2 Surgical Treatment Recommendations for Complications Related to Peptic Ulcer Disease

Bleeding:

- Gastric: Partial gastrectomy or oversewing of bleeding vessel with treatment of *Helicobacter pylori*
- Duodenal: Oversewing of bleeding vessel with treatment of *H. pylori*

Perforation: Patch closure with treatment of *H. pylori*

Obstruction: Rule out malignancy followed by gastrojejunostomy with treatment of *H. pylori*

Intractable: Truncal vagotomy ± antrectomy

PUD and improved medical management, the surgeon's role now is primarily to treat the patients who have a complication from their disease. Complicated PUD includes hemorrhage, perforation, and obstruction (Box 86.2). Frequently included in discussions of complicated ulcer disease is an intractable ulcer. Although intractable disease no doubt exists, its definition is nebulous, and determining exactly when and what type of surgical intervention is required is primarily a matter of judgment. In the current era of excellent treatment options for *H. pylori* infection and acid suppression, few patients who are truly compliant with medical therapy develop intractable ulcer disease in the absence of malignancy or another underlying cause such as ZES. Early multidisciplinary management is imperative for patients with complicated PUD to ensure optimal patient outcomes.

Hemorrhage. PUD is the most common cause of upper GI bleeding, accounting for roughly 35% to 50% of cases; bleeding occurs in 15% to 20% of patients with PUD.[20] The predominant risk factor for PUD bleeding is NSAID use; *H. pylori* infection, older age, significant medical comorbidities, and anticoagulant use are other known risks. Patients can present with hematemesis, melena, or both. The initial approach to an upper GI bleed from PUD is similar to the approach to other patients presenting with acute hypovolemic blood loss. Large-bore intravenous (IV) access, rapid restoration of intravascular volume with fluid and blood products as the clinical situation dictates, and close monitoring of vital signs are all essential to effective management of these patients. Patients should be initiated on an IV PPI during their initial evaluation. The role of NG lavage is controversial and is no longer routinely recommended, as no clinical benefit has been shown with its use.[21] Additionally, the use of a prokinetic such as erythromycin before endoscopy can improve mucosal visualization as well as NG lavage.

Upper flexible endoscopy is the best initial procedure for diagnosis of the source of upper GI bleeding and for therapeutic intervention, including in the setting of bleeding peptic ulcers. Patients with an acute upper GI bleed should undergo endoscopy within 24 hours. Patients who are noted on endoscopy to have active bleeding or a visible vessel within the ulcer require endoscopic therapy. Patients without active bleeding, no visible vessel, and a clean ulcer base are low risk and do not require further intervention. There is no consensus on endoscopic intervention for patients with an adherent clot that does not dislodge after vigorous irrigation.[22] The most commonly used system for classifying the endoscopic appearance of bleeding ulcers is the Forrest classification (Table 86.4), which stratifies the risk of rebleeding based on observed "stigmata of recent hemorrhage."[23] All patients undergoing endoscopic examination should be tested for *H. pylori* status with either urease assay, histology, or culture. Endoscopic treatment options include hemostatic clips, electrocoagulation, argon plasma coagulation, heater probe, and absolute ethanol injection. Epinephrine injection should not be used as monotherapy but can be used in combination with another therapeutic method.

A randomized trial compared 241 patients with high-risk bleeding ulcers (defined in this study as 2 cm in size or greater, active bleeding during endoscopy, hemoglobin levels less than 9 g/dL, or hypotensive shock) after control endoscopically to receive either angiographic embolization or standard treatment. The primary end point was recurrent bleeding within 30 days. There was no significant difference in rebleeding rates with prophylactic embolization (10% vs. 11%). Mortality was also similar with an overall mortality in the study of 3%.[24]

Patients who have a second episode of bleeding after initially successful endoscopic therapy are typically treated with repeat endoscopy. Patients with recurrent bleeding can be considered for interventional angiography with transarterial embolization (Fig. 86.9) if they are hemodynamically stable and those resources and expertise are available.

All high-risk patients should be placed in a monitored setting. Although prior consensus guidelines advocated for continuous IV PPI infusion, a systematic review and meta-analysis showed intermittent high-dose PPI therapy was comparable to continuous infusion for patients with endoscopically treated high-risk bleeding ulcers.[25] IV PPI therapy should be initiated on patient presentation and is recommended for 3 days after endoscopy and then oral PPI for at least 2 weeks. A longer duration of PPI treatment may be needed depending on the underlying clinical scenario.[22]

TABLE 86.4 Forrest Classification of Stigmata of Recent Hemorrhage on Endoscopic Examination of Peptic Ulcers and Relative Prevalence

STIGMATA OF RECENT HEMORRHAGE	FORREST CLASSIFICATION	PREVALENCE	RISK OF REBLEEDING
Active bleeding			
Active spurting	IA	10%	90%
Active oozing	IB	10%	10%–20%
Recent hemorrhage			
Nonbleeding, visible vessel	IIA	25%	50%
Adherent clot	IIB	10%	25%–30%
Flat pigmented spot	IIC	10%	5%–10%
No signs of hemorrhage			
Clean-based ulcer	III	35%	3%–5%

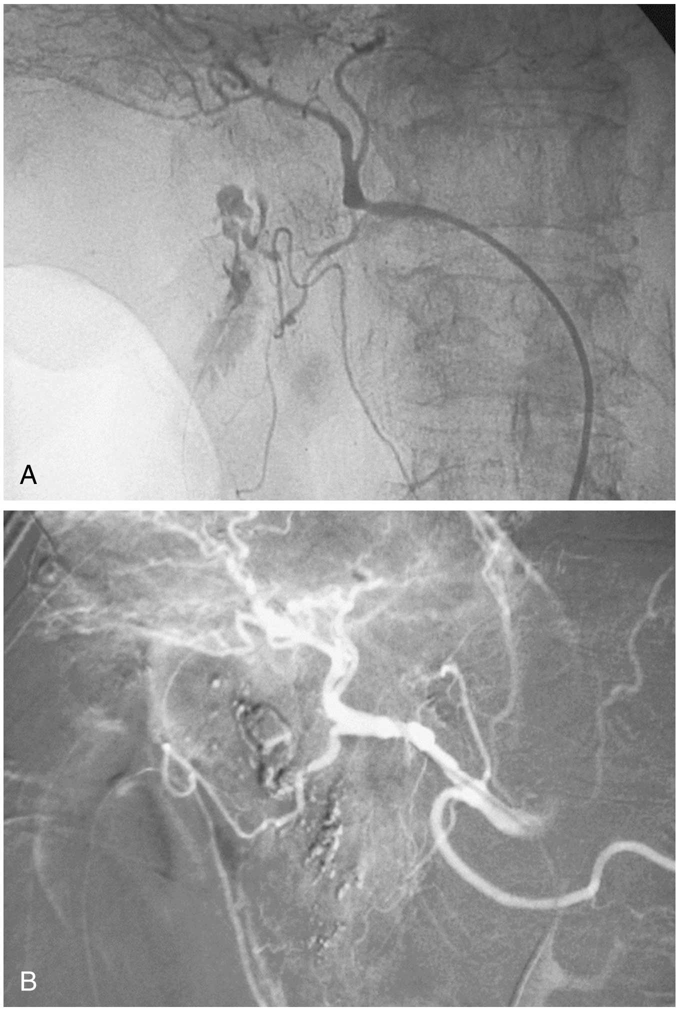

FIGURE 86.9 Endovascular control of a bleeding duodenal ulcer. (A) An angiogram is obtained, which shows extravasation from a branch off of the gastroduodenal artery. (B) A completion angiogram after glue embolization of the vessel shows resolution of the bleed with preservation of flow through the gastroduodenal artery. (From Loffroy R, Guiu B, Cercueil JP, et al. Refractory bleeding from gastroduodenal ulcers: arterial embolization in high-operative-risk patients. *J Clin Gastroenterol.* 2008;42:361-367.)

Despite the use of PPIs and improved methods of nonoperative control, some patients will require surgical intervention. Indications for surgical intervention include hemodynamic instability, failed endoscopic treatment, or recurrent hemorrhage after multiple endoscopic and/or interventional radiology treatments. The vessel most likely to be bleeding is the gastroduodenal artery because of a posterior duodenal ulcer erosion. Although bleeding duodenal ulcers can be treated laparoscopically, the more typical approach is through an upper midline laparotomy, especially in patients who are hemodynamically unstable. A Kocher maneuver is performed to mobilize the duodenum. The anterior wall of the duodenal bulb is opened longitudinally, and the incision can be carried across the pylorus if needed. The gastroduodenal artery is oversewn with a three-point U stitch technique, which effectively ligates the main vessel (superior and inferior stitches) and prevents back-bleeding from any smaller branches (medial stitch), such as the transverse pancreatic artery, that head to the patient's left toward the body of the pancreas. One must be careful to avoid incorporating the common bile duct into the stitch. The course of the common bile duct can be identified by inserting a probe through the ampulla of Vater transduodenally or performing an intraoperative cholangiogram. Hemostasis should be confirmed before duodenal closure. The duodenotomy is closed transversely to avoid narrowing. Surgery for a bleeding gastric ulcer typically includes partial gastrectomy with either Billroth I or II reconstruction. If the patient is hemodynamically stable, a careful preoperative history should be taken to assess if the patient may benefit from concurrent truncal vagotomy, though this should not be performed in unstable patients. If the gastric ulcer is not resected and the bleeding is controlled with suture ligature, biopsy at the time of surgery is necessary to exclude malignancy.

Perforation. Patients with perforation from PUD typically report sudden-onset, severe epigastric pain. They frequently have free air visible on the chest radiograph and have localized peritoneal signs on examination. Patients with more widespread spillage will have diffuse peritonitis. Perforation is a less frequent complication of PUD, occurring at about one-sixth the incidence of bleeding. However, perforation has the highest mortality rate of any complication of ulcer disease, reported as high as 30%.[20]

Perforation necessitates emergent surgical consultation. Initial empiric antibiotic therapy should cover enteric gram-negative rods, anaerobes, and mouth flora and should be based on local susceptibility patterns when available. Upright x-ray can be obtained to assess for free air, but CT scan with oral and IV contrast has higher sensitivity for diagnosis. Patients with localized symptoms, in stable clinical condition, and with a water-soluble contrast study confirming a sealed leak can be considered for nonoperative management. An early description of nonoperative management of perforated PUD was made by Herman Taylor in the 1940s. At that time nonoperative treatment consisted of NG decompression, IV fluid resuscitation, and serial abdominal x-rays. Currently, nonoperative management (often referred to as *Taylor's method*) should consist of close hemodynamic monitoring, serial abdominal examinations, nil per os with NG tube, broad-spectrum IV antibiotics, and IV PPI. This can be effective in well-selected patients. For example, in a retrospective series of 64 patients managed nonoperatively with small-volume perforated peptic ulcers, 89% of patients successfully avoided intervention and only 4 required surgical drainage of the abscess.[26] Small series of patients treated endoscopically have been published but at this time is not standardly used.

At surgery, the perforation usually can easily be accessed through an upper midline incision. Perforations smaller than 2 cm can generally be closed primarily and buttressed with the omentum or falciform ligament. For larger perforations or ulcers with fibrotic edges that cannot be brought together without tension, a Graham patch repair with healthy omentum is performed. Multiple stay sutures are placed that incorporate healthy tissue on the proximal and the distal sides of the ulcer. The omentum is placed underneath these sutures, and they are tied to secure it in place and seal the perforation (Fig. 86.10). A modification of the Graham patch repair involves closing the perforation first with sutures, placing the omentum over the now closed perforation, and securing the omentum by tying knots a second time with the same suture. A meta-analysis of eight randomized trials including 615 patients compared laparoscopic omental patch repair with open repair. This showed that laparoscopic surgery was associated with less postoperative pain and fewer wound infections with equivalent leak rates and mortality.[27] In stable patients with small

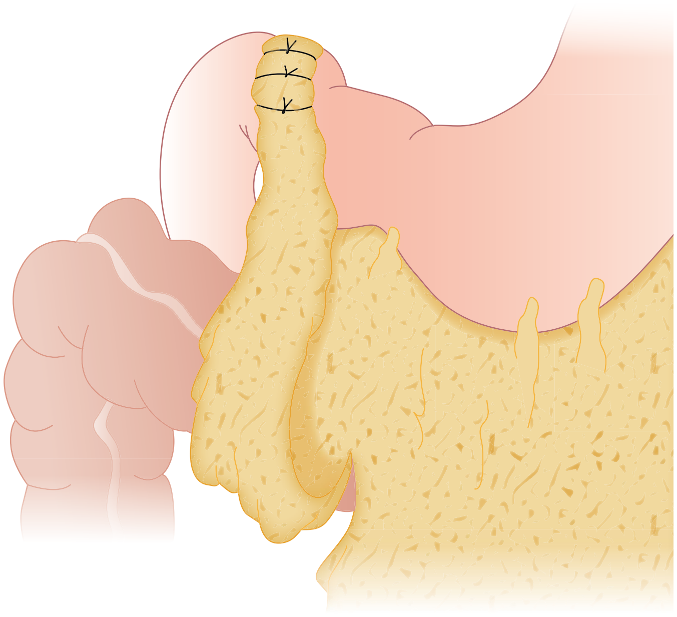

FIGURE 86.10 Graham patch repair of a perforated duodenal ulcer. A "tongue" of omentum is brought up to cover the ulcer defect and secured in position with a series of interrupted sutures. In Graham's original description, the ulcer defect is not closed, but if the tissue edges are healthy and come together without undue tension, a primary closure can be performed and reinforced with an omental patch. (From Baker RJ. Perforated duodenal ulcer. In: Baker RJ, Fischer JE, eds. *Mastery of Surgery*. London: Little, Brown, and Company; 2001:969.)

perforations, laparoscopic repair is thus preferred if the surgeon has adequate technical experience to perform this safely.

For very large perforations (>2 cm), control of a duodenal defect can be difficult and there is no standardized approach. The defect should be closed by the application of healthy tissue, such as omentum or jejunal serosa from a Roux-en-Y–type limb. In such cases, a pyloric exclusion is typically performed by oversewing the pylorus using absorbable suture or stapling across the pylorus using a noncutting linear stapler. A gastrojejunostomy is created to bypass the duodenum in a Billroth II or Roux-en-Y fashion. Over several weeks, the pyloric exclusion stitches or staples give way, restoring normal GI anatomy after the perforation site has been given time to heal. Alternatively, a duodenostomy tube can be placed through the perforation with wide peritoneal drainage. An alternative in this difficult situation is antrectomy and a Billroth II or Roux-en-Y reconstruction to include the duodenal ulcer if the duodenal stump has healthy tissue and there is sufficient distance from the ampulla of Vater. Feeding jejunostomy placement should be considered at time of operation for enteral nutrition access.

Perforated gastric ulcers are managed based on their location. Given their association with malignancy, resection is generally preferred when possible. Partial gastrectomy with reconstruction is performed if the patient is stable without significant comorbidities. Either wedge resection or patch closure can also be performed depending on the clinical situation; biopsies should be obtained in cases of patch closure to rule out malignancy.

For patients who are known to be negative for *H. pylori,* who are taking long-term NSAIDs that they cannot discontinue, or who have failed medical therapy in the past for their ulcer disease, an acid-reducing procedure can be added at the time of repair if the patient is stable. These procedures are discussed elsewhere in this chapter and must be based on the clinical situation and comfort of the surgeon. All *H. pylori*–positive patients should undergo eradication postoperatively with appropriate triple or quadruple therapy regimens.

Gastric outlet obstruction. Acute and chronic inflammation of the duodenum or pylorus can lead to mechanical gastric outlet obstruction. Chronic inflammation leads to recurrent episodes of injury and healing. This ultimately leads to fibrosis, scarring, and stenosis of the outflow tract. The stomach can become massively dilated and lose its muscular tone. Patients will present with early satiety, anorexia, weight loss, nausea, and vomiting. In cases of prolonged vomiting, patients often become dehydrated and can develop a hypochloremic, hypokalemic metabolic alkalosis.

Initial management should involve gastric decompression with NG tube placement and correction of fluid and electrolyte abnormalities. Nutritional status should be assessed. Gastric outlet obstruction from PUD is not a surgical emergency, and full diagnostic workup before any surgical intervention is necessary, especially as gastric cancer is now a more common cause of this disorder. Upper endoscopy should be performed to rule out a malignancy and test for *H. pylori* infection.

Endoscopic dilation and *H. pylori* eradication are the mainstays of initial therapy for PUD gastric outlet obstruction. Other endoscopic techniques, including self-expanding metal stents, ultrasound-guided gastric bypass, and POEM, have also been reported; decisions between these endoscopic interventions and surgery should be done in a multidisciplinary fashion. Surgery entails primary antrectomy with resection of the obstructing portion and vagotomy. Another surgical option, especially when there is significant duodenal inflammation or scarring present, is vagotomy with a drainage procedure, typically either a Jaboulay gastroduodenostomy or a gastrojejunostomy.

Refractory peptic ulcer disease. Refractory PUD is defined as failure of an ulcer to heal after an initial trial of 8 to 12 weeks of PPI therapy or if patients relapse after therapy has been discontinued; it is estimated to occur in 5% to 10% of patients. Benign gastric ulcers that persist must be evaluated for malignancy. Additionally, other less common sources of ulceration such as ZES, Crohn disease, or sarcoidosis should be considered. For any refractory ulcer, adequate duration of antisecretory therapy, *H. pylori* eradication, and elimination of NSAID use must be confirmed. A fasting serum gastrin level should be obtained to rule out gastrinoma. Although rarely seen today, truly intractable ulcer disease that fails medical management should be treated with a vagotomy, with or without an antrectomy.

Surgical procedures for peptic ulcer disease. Elective operative intervention for PUD has become rare as medical therapy has improved. The recognition of *H. pylori* and its eradication suggest that the refractory indication for surgery may apply only to patients in whom the organism cannot be eradicated, who cannot be taken off NSAIDs, who cannot tolerate their medical regimen, or who have a rarer cause of PUD. Patients who are noncompliant with acid suppression therapy may also fall into this category, but this is more controversial.

The goal of operative ulcer therapy is to resect or promote ulcer healing and to reduce gastric acid secretion. Surgical gastric acid reduction can be accomplished by removing vagal stimulation via vagotomy, gastrin-driven secretion by performing an antrectomy, decreasing the number of parietal cells with a subtotal gastrectomy, or a combination procedure. Vagotomy decreases peak acid output by approximately 50% to 70%, whereas vagotomy plus antrectomy decreases peak acid output by approximately 85%. These surgeries can be performed either open or minimally invasively. Pathologic confirmation of resected vagal trunks should be performed.

Truncal vagotomy. Truncal vagotomy is performed by dividing the left and right vagus nerves above the hepatic and celiac branches, just above the GE junction (see Fig. 86.3). The vagal nerves should be clipped or ligated proximally and distally with at least 2 cm resected. Pyloric relaxation is mediated by vagal stimulation, and a vagotomy without a drainage procedure can cause delayed gastric emptying. Truncal vagotomy in combination with a Heineke-Mikulicz pyloroplasty is shown in Fig. 86.11. When the duodenal bulb is scarred, a Finney pyloroplasty or Jaboulay gastroduodenostomy may be a useful alternative. Significant scarring or inflammation may necessitate a gastrojejunostomy. In general, there is little difference in the side effects associated with the type of drainage procedure performed, although bile reflux may be more common after gastroenterostomy, and diarrhea is more common after pyloroplasty. The incidence of dumping syndrome is similar for both.

Selective vagotomy. Selective vagotomy divides the main right and left vagus nerves just distal to the celiac and hepatic branches (see Fig. 86.3). A pyloric drainage procedure is also performed. However, selective vagotomy results in higher ulcer recurrence rates than truncal vagotomy, with no advantage in terms of decreased postgastrectomy symptoms. For these reasons, selective vagotomy has largely been abandoned.

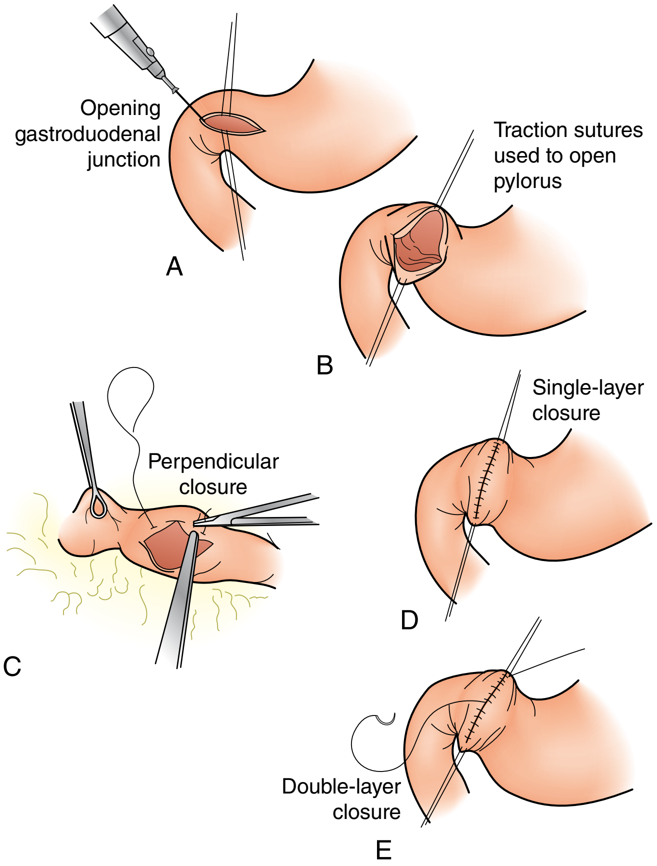

FIGURE 86.11 (A–E) Heineke-Mikulicz pyloroplasty. (From Soreide JA, Soreide A. Pyloroplasty. *Oper Tech Gen Surg.* 2003;5:65-72.)

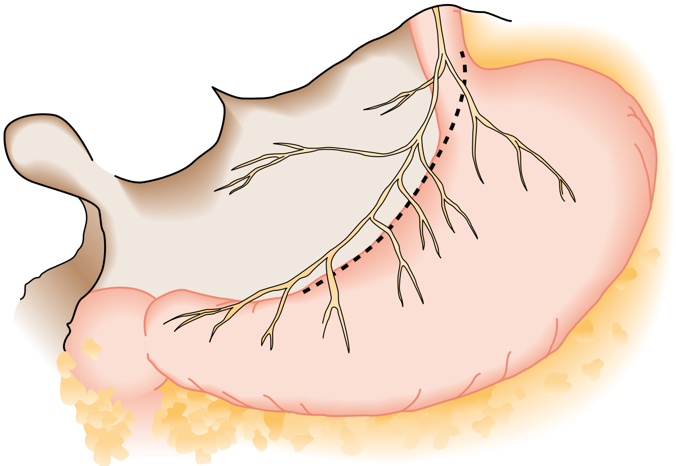

FIGURE 86.12 Anterior view of the stomach and anterior nerve of Latarjet. Note the line of dissection for parietal cell or highly selective vagotomy *(dashed line)*. The last major branches of the nerve are left intact, and the dissection begins 7 cm from the pylorus. At the gastroesophageal junction, the dissection is well away from the origin of the hepatic branches of the left vagus. (From Kelly KA, Teotia SS. Proximal gastric vagotomy. In: Baker RJ, Fischer JE, eds. *Mastery of Surgery.* Philadelphia: Lippincott Williams & Wilkins; 2001:943.)

Highly selective vagotomy. Highly selective vagotomy is also referred to as a *parietal cell vagotomy*. A highly selective vagotomy divides only the vagus nerve branches supplying the acid-producing portion of the stomach within the corpus and fundus. This procedure preserves the vagal innervation of the gastric antrum and pylorus, so there is no need for routine drainage procedures. In general, the nerves of Latarjet are identified anteriorly and posteriorly, and the crow's feet innervating the fundus and body of the stomach are divided. These nerves are divided up until approximately 7 cm proximal to the pylorus, the area in the vicinity of the gastric antrum. Superiorly, division of these nerves is carried to a point at least 5 cm proximal to the GE junction on the esophagus (Fig. 86.12). The criminal nerve of Grassi represents a very proximal branch of the posterior vagus trunk; great attention is needed to avoid missing this branch in the division process because it is frequently cited as a reason for ulcer recurrence if left intact.

The ulcer recurrence rates after highly selective vagotomy are variable and depend on the skill of the surgeon. Lengthy longitudinal follow-up is necessary to evaluate the results of this procedure. Recurrence rates of 10% to 15% have been reported for this procedure when performed by a skilled surgeon. These rates are slightly higher than the rates reported after truncal vagotomy in combination with pyloroplasty; however, highly selective vagotomy has lower rates of postvagotomy dumping syndrome and diarrhea. This operation is less frequently performed today given the decreasing need for elective PUD surgery.

Truncal vagotomy and antrectomy. Antrectomy is generally not performed for duodenal ulcers and is more commonly performed for gastric ulcers. Relative contraindications include cirrhosis, extensive scarring of the proximal duodenum that leaves a difficult or tenuous duodenal closure, and previous operations on the proximal duodenum. When done in combination with truncal vagotomy, it is more effective at reducing acid secretion and recurrence than truncal vagotomy in combination with a drainage procedure or highly selective vagotomy. The recurrence rate for ulceration after truncal vagotomy and antrectomy is 0% to 2%. However, this low recurrence rate needs to be balanced against the

20% rate of postgastrectomy and postvagotomy syndromes, longer operative times, and increased postoperative morbidity.

Antrectomy requires mobilization of the distal stomach with division of the right gastroepiploic and right gastric arteries. The left gastric and left gastroepiploic vessels should be preserved. The stomach is divided just proximal to the incisura angularis, and the first portion of the duodenum is divided just distal to the pylorus. Reconstruction of GI tract can be accomplished by a gastroduodenostomy (Billroth I procedure [Fig. 86.13]) or gastrojejunostomy (either Billroth II procedure [Fig. 86.14] or Roux-en-Y reconstruction). For benign disease, gastroduodenostomy is generally favored because it avoids the risks of retained antrum syndrome, duodenal stump leak, and afferent loop obstruction associated with gastrojejunostomy after resection. Retained antrum syndrome is a result of incomplete antrectomy; residual G cells are no longer exposed to gastric acid, leading to hypergastrinemia with resultant stimulation of acid production and marginal ulceration at the gastrojejunostomy. If the duodenum is significantly scarred, gastroduodenostomy may not be technically feasible, necessitating a gastrojejunostomy. The gastric anastomosis is typically placed in a dependent portion of the stomach to facilitate drainage, often along the posterior wall of the greater curvature. A retrocolic anastomosis minimizes the length of the afferent limb and decreases the likelihood of twisting or kinking that could lead to afferent loop obstruction and duodenal stump leak.

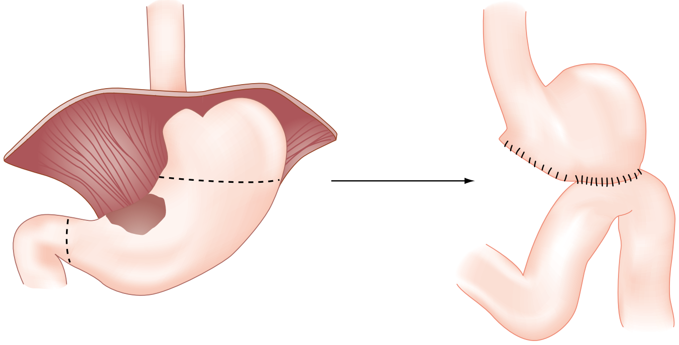

FIGURE 86.14 Subtotal gastrectomy with a Billroth II anastomosis.

Partial gastrectomy. Partial, or subtotal, gastrectomy removes both gastrin-producing and acid-secreting cells. Reconstruction is necessary after a subtotal gastrectomy, with Billroth II or Roux-en-Y being the most commonly used. Billroth I reconstruction is typically difficult because of the underlying inflammation and amount of mobilization that would be required to create a tension-free anastomosis.

Zollinger-Ellison syndrome. ZES was first described in 1955 and is a clinical triad consisting of gastric acid hypersecretion, severe PUD, and gastrin-producing neuroendocrine tumors (gastrinomas). The hypergastrinemia associated with ZES accounts for most, if not all, clinical symptoms experienced by patients. Patients may also exhibit diarrhea, weight loss, steatorrhea, and esophagitis. Endoscopy frequently demonstrates prominent gastric rugal folds, reflecting the trophic effect of hypergastrinemia on the gastric fundus. Approximately 20% to 30% of patients have ZES as part of multiple endocrine neoplasia (MEN) type 1, an autosomal dominant syndrome. Thus, any patient found to have ZES should have serum parathyroid hormone, ionized calcium, and prolactin levels checked.

The initial diagnostic test to evaluate for ZES is a fasting serum gastrin level. Most patients with gastrinoma have elevated fasting serum gastrin levels ($>$200 pg/mL), and values higher than 1000 pg/mL are diagnostic in the setting of gastric pH $<$2. Diagnosing ZES in patients with marginally elevated gastrin levels is difficult because PPI use, *H. pylori* infection, and renal failure all can cause an elevation of fasting serum gastrin. Additionally, gastric pH testing is not frequently obtained. In patients with equivocal gastrin levels, the most sensitive diagnostic test is the secretin-stimulated gastrin level. Serum gastrin samples are measured before and after IV secretin administration. An increase in the serum gastrin level of greater than 200 pg/mL above basal levels is suggestive of gastrinoma versus other causes of hypergastrinemia, which normally do not demonstrate this response. Other supportive tests include ^{68}Ga-DOTATATE PET/CT, known or suspected MEN1 syndrome, and a positive biopsy for neuroendocrine tumor.[28]

Acid suppression therapy is initiated after diagnosis of gastrinoma, preferably with a high-dose PPI. Medical management is indicated preoperatively and for patients with metastatic or unresectable gastrinoma. The next step in management is localization and staging of the tumor. Most ZES gastrinomas are located in the duodenum or pancreas, within the "gastrinoma triangle." The points of this triangle are made up of the cystic–common bile duct junction, the pancreas body-neck junction, and the junction between the second and third portions of the duodenum. The initial imaging study to localize the gastrin-secreting tumor is either triple-phase CT or MRI of the abdomen. Somatostatin receptor imaging, most often ^{68}Ga-DOTATATE PET/CT, is increasingly being used to aid in diagnosis and localization of neuroendocrine tumors, including gastrinomas. If cross-sectional imaging is nondiagnostic, endoscopic ultrasound (EUS) can be performed. If one is still unable to localize the tumor, patients can be offered a surgical exploration.

Localized gastrinomas should be resected whenever possible. The exception is gastrinomas less than 2 cm in patients with MEN1. Once the tumor is located intraoperatively, a resection according to oncologic principles should be performed (rather than a tumor enucleation) with at least 10 lymph nodes removed. Patients with advanced or metastatic disease can be treated with a variety of treatments, and there is no standardized algorithm at this time. Surgical re-resection can be considered in cases of recurrent disease. Systemic therapies include somatostatin analogs, everolimus, and cytotoxic chemotherapy. Peptide receptor radionuclide therapy (PRRT) delivers radiolabeled somatostatin analogs systemically. PRRT has been shown to have significantly improved progression-free survival and a nonsignificant trend toward improved overall survival in patients with advanced neuroendocrine tumors compared with octreotide alone, though this was not specifically studying patients with gastrinoma.[29] For patients with liver-only metastases, liver-directed therapies (radiofrequency ablation, cryoablation, transarterial embolization, resection/debulking, or liver transplantation) can be considered in a multidisciplinary setting.

STRESS GASTRITIS

Stress ulceration is defined as an upper GI tract ulcer occurring because of hospitalization and most commonly occurs in the stomach. Stress gastritis can occur after physical trauma, shock, sepsis, hemorrhage, or respiratory failure and may lead to life-threatening gastric bleeding. Stress gastritis is characterized by multiple superficial (nonulcerating) erosions that typically begin in the proximal portion of the stomach and progress distally. They may also occur in the setting of a central nervous system disease elevating intracranial pressure with resultant vagal nerve stimulation (Cushing ulcer) or as a result of thermal burn injury involving more than 20% to 30% of the body surface area leading to gastric ischemia (Curling ulcer).

Stress gastritis lesions can change over time. Early lesions are typically multiple and shallow, with discrete areas of erythema along with focal hemorrhage or adherent clot. These early lesions can develop within the first hours of major trauma or illness. If the lesion erodes into the submucosa, significant bleeding may result. They are almost always seen in the fundus or body of the stomach and only rarely in the distal stomach. Late lesions appear identical to regenerating mucosa around a healing gastric ulcer. Both early and late lesions can be seen endoscopically.

Pathophysiology

Although the precise mechanisms responsible for the development of stress gastritis remain to be fully elucidated, evidence suggests a multifactorial cause related to an imbalance between acid production and mucosal protection. Examples of impaired mucosal defense mechanisms against luminal acid are reduction in blood flow, mucus, or bicarbonate secretion by mucosal cells or decreased endogenous prostaglandins. All these factors render the stomach more susceptible to damage from luminal acid, with the resultant hemorrhagic gastritis. Stress is considered present when hypoxia, sepsis, or organ failure occurs. When stress is present, mucosal ischemia is thought to be the main factor responsible for the breakdown of these normal defense mechanisms. Although increased gastric acid secretion rarely occurs in this situation, the presence of luminal acid appears to be a prerequisite for this form of gastritis to evolve.

A seminal Canadian multicenter cohort study of patients admitted to the intensive care unit (ICU) sought to identify risk factors for clinically important stress ulceration, defined as overt bleeding associated with hemodynamic compromise or need for blood transfusion.[30] Of 2252 patients, only 30% received stress ulcer prophylaxis and 1.5% developed clinically important bleeding. Two risk factors were significant on multivariable regression: mechanical ventilation for over 48 hours (odds ratio 15.6) and coagulopathy (odds ratio 4.3). Coagulopathy was defined as platelet count less than 50,000, international normalization ratio (INR) greater than 1.5, or partial thromboplastin time (PTT) greater than two times normal. Other reported risk factors for stress gastritis include liver or kidney failure, shock, sepsis, trauma, severe burn, use of antiplatelets or NSAIDs, and prior history of GI bleeding. Initiation of enteral nutrition, along with its other beneficial effects in critically ill patients, has been shown to decrease the risk of stress ulceration.[31]

Presentation and Diagnosis

Stress gastritis develops within 1 to 2 days after a traumatic event or critical illness in more than 75% of patients historically,[30] though the majority of patients have minimal or no related symptoms. The only clinical sign may be painless upper GI bleeding or anemia. The bleeding is usually slow and intermittent. Overt bleeding is defined as hematemesis, frank blood in NG aspirate, or melena. Clinically significant or clinically important bleeding is defined as overt bleeding with the addition of either hypotension, transfusion requirement, or need for therapeutic intervention. The rate of clinically significant bleeding in critically ill patients from stress ulceration has been reported from 1% to 3%. Although upper endoscopy is required to definitively confirm the diagnosis and differentiate stress gastritis from other sources of GI hemorrhage, it is often unnecessary in patients with asymptomatic or minimally symptomatic manifestations.

Prophylaxis

Development of hemodynamically significant stress gastritis substantially increases mortality in critically ill patients. The decision whether or not to give stress ulcer prophylaxis in high-risk patients is being actively studied. Historically, stress ulcer prophylaxis was routinely given in the ICU, but more recent guidelines suggest only administering prophylaxis to those at high risk of developing stress ulceration. However, the precise definition of what features constitute high risk is also debated.

A European multicenter trial randomized 3298 patients admitted to the ICU to either receive 40 mg IV pantoprazole or placebo during their ICU stay. The primary outcome was 90-day mortality, which was statistically similar between the two groups (31.1% in the PPI group and 30.4% in the placebo group). Pantoprazole did have a lower rate of clinically important GI bleeding at 2.5% compared with 4.2%, but no *p*-values were reported on secondary outcomes to avoid adjustment for multiple comparisons. Infectious complications were also similar.[32] A multicenter trial that included 50 ICUs across five countries randomized 26,982 patients who required mechanical ventilation within 24 hours of ICU admission to either PPI or H_2 receptor antagonist stress ulcer prophylaxis. The primary outcome was 90-day mortality, which was similar at 18% in the PPI group and 17% in the H_2 receptor antagonist group. There was a slightly lower rate of clinically important upper GI bleeding in favor of the PPI group (1.3 vs. 1.8%, $p = 0.009$). However, this is difficult to interpret given that over 20% of the patients randomly assigned H_2 receptor antagonist therapy received a PPI.[33]

There have been multiple systematic reviews and meta-analyses assessing the efficacy of stress ulcer prophylaxis. One recent network meta-analysis included 72 randomized trials with 12,660 patients.[34] For patients at highest risk (>8%) or high risk (4%–8%) of bleeding, both PPIs and H_2 receptor antagonists reduced clinically important GI bleeding compared with placebo or no prophylaxis with odds ratios of 0.61 and 0.46, respectively. However, neither had an effect on mortality compared with placebo. Earlier data suggested that stress ulcer prophylaxis correlated with increased frequency of *Clostridioides difficile* and nosocomial pneumonia infections; however, more recent trials and meta-analyses are conflicting.

Patients at high risk for stress gastritis should be treated prophylactically to minimize their incidence of clinically significant bleeding, though the exact definition of what constitutes high risk is still debated and no clear guidelines exist. Because mucosal ischemia may alter many mucosal defense mechanisms that enable the stomach to withstand luminal irritants and protect itself from injury, every effort should be made to correct any perfusion deficits secondary to shock. If prophylaxis is deemed indicated, a PPI or H_2 antagonist should be used, with most institutions favoring PPI.

Treatment

Improvements in critical care resuscitation, prophylaxis for high-risk patients, and nonoperative interventions with endoscopy or angiography have significantly decreased the need for surgical intervention for gastric stress ulceration. Any patient with upper GI bleeding requires resuscitation with correction of any coagulation or platelet abnormalities, adequate IV access, blood availability, and close hemodynamic monitoring. Where available, thromboelastography (TEG) or rotational thromboelastometry (ROTEM) can be useful diagnostic adjuncts. An NG tube should be placed if not already present and IV PPI therapy started promptly. NG lavage can help remove blood and clots from the stomach, and NG decompression will decrease gastrin production. Sepsis is a common cause of stress gastritis, and if there is clinical concern, broad-spectrum antibiotics should be promptly initiated.

Upper endoscopy is typically the first-line intervention for upper GI bleeding and should be performed for both diagnosis and treatment. Treatment can include coagulation therapy, hemostatic clipping, or injection therapy depending on the clinical scenario and endoscopist expertise. Bleeding associated with stress gastritis is typically diffuse without a single discrete bleeding source; thus, rebleeding rates are high. In hemodynamically stable patients at centers with available resources, angiography is another diagnostic and therapeutic option. If a single arterial source of bleeding is identified, embolization can be performed. Catheter-directed vasopressin into the left gastric artery can temporize diffuse bleeding from stress gastritis. The usual dose is up to 0.4 pressor units/minute. The infusion is either continued in the ICU or embolization is performed given the risk of rebleeding after vasopressin discontinuation. Catheter-directed vasopressin can cause peripheral vasoconstriction and bradyarrhythmia and should be avoided in patients with a history of heart disease.

Surgical intervention for stress gastritis is required in patients with hemodynamic instability from hemorrhage, persistent bleeding not amenable to nonsurgical interventions, or in rare instances of gastric perforation from stress ulceration. The surgical intervention is individualized based on the patient's clinical status. Temporary abdominal closure followed by a second-look laparotomy can be used because many patients are coagulopathic. Because most lesions are in the proximal stomach or fundus, a long anterior gastrotomy should be made in this area. The gastric lumen is cleared of blood, and the mucosal surface is inspected for bleeding points. All bleeding areas are oversewn with figure-of-eight stitches taken deep within the gastric wall. Most superficial erosions are not actively bleeding and do not require ligation unless a blood vessel is seen at its base. In hemodynamically stable patients, the operation is completed by closing the anterior gastrotomy in two layers and performing a truncal vagotomy and pyloroplasty to reduce acid secretion. Less commonly, a partial gastrectomy is performed if persistent bleeding occurs from only a portion of the stomach. Before the advent of PPIs and nonsurgical therapies, total gastrectomy and gastric devascularization were described; however, these should rarely be performed in the present day and only considered in patients with life-threatening hemorrhage refractory to other forms of therapy. Gastric devascularization involves ligating the left and right gastric and the left and right gastroepiploic arteries. Because of collateral circulation, this does not always lead to full-thickness necrosis in patients who have not had prior foregut surgery. Patients with a perforation from stress ulceration should be managed with either closure or resection of the perforated region depending on intraoperative assessment and consideration of truncal vagotomy and pyloroplasty based on the patient's clinical stability.

POSTGASTRECTOMY SYNDROMES

Gastric surgery can result in numerous physiologic derangements caused by loss of reservoir function, interruption of the pyloric sphincter mechanism, and vagal nerve transection. The GI and cardiovascular symptoms may result in disorders collectively referred to as *postgastrectomy syndromes.* The physiologic changes are not specific to the underlying disease for which the surgery was indicated, occurring after gastrectomy for PUD, oncologic resection, or obesity surgery. Approximately 1% to 5% of patients become permanently disabled from their postgastrectomy symptoms.

Dumping Syndrome

Dumping syndrome is a constellation of symptoms caused by rapid postprandial gastric emptying that can be divided into two categories: early and late. This symptom complex can develop after any operation on the stomach but is most common after partial gastrectomy with the Billroth II reconstruction. It is less commonly observed after Billroth I or Roux-en-Y reconstruction or after vagotomy and drainage procedures. International consensus definition of early dumping syndrome is symptoms occurring within 1 hour of a meal, though most effects are seen within 30 minutes.[35] GI symptoms include abdominal pain, early satiety, nausea/vomiting, diarrhea, and bloating. Vasomotor systemic symptoms include diaphoresis, tachycardia, palpitations, headache, and syncope. Early dumping syndrome is a result of rapid passage of high-osmolarity food from the stomach into the small intestine. The hypertonic food bolus induces a rapid shift of extracellular fluid into the intestinal lumen to achieve isotonicity, leading to luminal distention. Several hormones are also stimulated for release, including neurotensin, VIP, glucagon-like peptide-1 (GLP-1), insulin, and glucagon.

Late dumping syndrome occurs 1 to 3 hours after a meal and is less common than early dumping syndrome.[35] The basic defect of late dumping is also rapid gastric emptying; however, its symptoms are related specifically to carbohydrates being delivered rapidly into the proximal intestine. An exaggerated GLP-1 response is the key mediator in late dumping syndrome. When carbohydrates are delivered to the small intestine, they are quickly absorbed, resulting in hyperglycemia. This triggers the release of large amounts of insulin to control the increasing blood sugar level, but overcompensation of this normal physiologic mechanism results in hypoglycemia. This hypoglycemia activates the adrenal glands to release catecholamines, which results in diaphoresis, tremulousness, lightheadedness, tachycardia, and confusion.

The diagnosis of dumping syndrome is primarily a clinical one. When indicated, a modified oral glucose tolerance test can support the diagnosis. Patients ingest 75 g of a glucose solution after an overnight fast. This test is considered positive for early dumping syndrome if after 30 minutes there is an increase of the hematocrit by at least 3% or increase in heart rate of at least 10 beats/minute. The test is positive for late dumping syndrome if blood glucose is less than 50 mg/dL between 1 and 3 hours after ingestion. Gastric emptying tests have low sensitivity and specificity for dumping syndrome diagnosis and are not typically used.

Dietary measures are usually sufficient to treat most patients. These include avoiding foods containing large amounts of sugar, frequent feeding of small meals rich in protein and fiber, and separating liquids from solids during a meal. In some patients without a response to dietary measures, pharmacologic treatments directed at specific symptoms can be effective, such as tincture of opium or Imodium for diarrhea and meclizine for nausea. Small studies have shown that acarbose can reduce the incidence of hypoglycemia when taken with meals. Somatostatin analogs, such as octreotide, are the most studied pharmacologic treatment for dumping syndrome. These peptides not only inhibit gastric emptying but also slow small bowel transit and inhibit release of GI hormones and insulin. Somatostatin analogs are the preferred treatment option for patients with established dumping syndrome who fail to respond to dietary modification (with or without acarbose treatment).[35]

Patients with severe symptoms may require a reoperation if conservative dietary and medical management is unsuccessful. The choice of operation depends on the original gastric surgery. Pyloric reconstruction can sometimes be performed. For patients with a gastrojejunostomy without a gastrectomy, takedown of the gastrojejunostomy can be performed if the pylorus function is maintained. In patients with a prior Billroth II distal gastrectomy, converting the loop gastrojejunostomy to a Roux-en-Y reconstruction is recommended.

Metabolic Disturbances

Anemia is commonly seen in patients who have undergone a gastrectomy. Postgastrectomy anemia is related to iron or vitamin B_{12} deficiency. Iron is normally absorbed in the duodenum and proximal jejunum, so iron deficiency is more often seen after Billroth II and Roux-en-Y reconstruction than Billroth I. In general, the addition of iron supplements to the patient's diet corrects this problem. Vitamin B_{12} deficiency occurs secondary to poor absorption of dietary vitamin B_{12} because of the lack of intrinsic factor. Patients undergoing subtotal gastrectomy should be placed on lifelong vitamin B_{12} supplementation.

Osteoporosis has also been observed after gastric resection and is caused by deficiencies in calcium. If fat malabsorption is also present, the calcium malabsorption is aggravated further because fatty acids bind calcium. Bone disease generally develops approximately 5 years after surgery. Treatment of this disorder usually requires calcium supplements in conjunction with vitamin D. Patients with Billroth II or Roux-en-Y reconstruction that bypasses the duodenum should also receive supplementation of fat-soluble vitamins (vitamins A, D, E, and K).

Afferent Loop Syndrome

The afferent loop is the duodenojejunal loop proximal to the gastrojejunal anastomosis. Afferent loop syndrome is caused by mechanical obstruction of the afferent limb and often related to a long afferent limb. Pancreatic and hepatobiliary secretions accumulate within the limb, resulting in distention, epigastric discomfort, and cramping. The intraluminal pressure eventually increases enough to empty the contents of the afferent loop forcefully into the stomach, resulting in projectile bilious vomiting that offers immediate relief of symptoms. If the obstruction has been present for a long time, patients can develop blind loop syndrome. In this situation, bacterial overgrowth occurs in the static loop, and the bacteria bind with vitamin B_{12} and deconjugated bile acids; this results in a systemic deficiency of vitamin B_{12} (with the development of megaloblastic anemia), fat malabsorption, and deficiency in fat-soluble vitamins. Diagnosis of afferent loop syndrome is typically made with CT imaging showing a dilated afferent limb. Failure to visualize the afferent limb on upper endoscopy and failure of normal radionucleotide passage into the distal small bowel on hepatobiliary iminodiacetic acid (HIDA) scan are also suggestive of the diagnosis.

In the immediate postoperative setting, prompt correction is indicated to prevent bowel necrosis or duodenal stump blowout. A long afferent limb is usually the underlying problem, so treatment involves the elimination of this loop. Remedies include conversion of the Billroth II construction into a Billroth I anastomosis, enteroenterostomy between the afferent and efferent loops, and conversion to a Roux-en-Y reconstruction. Endoscopic enteroenterostomy or stenting are emerging options in centers with available expertise and in patients without concern for bowel ischemia.[36] Percutaneous enterostomy to drain the afferent limb has been described in patients with significant comorbidities in palliative settings.

Efferent Loop Obstruction

Obstruction of the efferent limb is rare. Efferent loop obstruction may occur at any time; however, the majority occur within the first postoperative month. Initial complaints may include left upper quadrant abdominal pain that is colicky in nature, bilious vomiting, and abdominal distention. The diagnosis is usually established by an upper GI series or CT with oral contrast, with failure of contrast to enter the efferent limb. Efferent obstructions can be caused by adhesions, strictures, jejunogastric intussusception, or retroanastomotic herniation. Operative intervention is almost always necessary and consists of reducing and closing the retroanastomotic hernia if this is the cause of the obstruction, anastomotic revision, or conversion to a Roux-en-Y reconstruction.

Alkaline Reflux Gastritis

After gastrectomy, reflux of bile is common. In a small percentage of patients, this reflux is associated with severe epigastric abdominal pain accompanied by bilious vomiting and weight loss. The diagnosis is typically made by careful history and exclusion of other causes. A technetium biliary scan can demonstrate reflux of bile into the stomach. Upper endoscopy demonstrates friable, beefy red mucosa.

Most patients with alkaline reflux gastritis have had gastric resection performed with a Billroth II anastomosis. Although bile reflux appears to be the inciting event, the exact pathogenesis is unclear. Most medical therapies that have been tried to treat alkaline reflux gastritis have not shown any consistent benefit. For patients with intractable symptoms, surgery is indicated. Revision options include Roux-en-Y reconstruction (with a Roux limb of 45–60 cm), Henley isoperistaltic jejunal interposition, or Braun enteroenterostomy.

Gastric Atony

Gastric emptying is delayed after truncal and selective vagotomies but not after a highly selective vagotomy. With selective or truncal vagotomy, patients lose their antral pump function and have a reduction in the ability to empty solids. In contrast, emptying of liquids is accelerated because of the loss of receptive relaxation in the proximal stomach. Although most patients undergoing vagotomy and a drainage procedure manage to empty their stomach adequately, some patients have persistent gastric stasis that results in retention of food within the stomach for several hours.

The diagnosis of gastric atony is confirmed by scintigraphic assessment of gastric emptying. However, other causes of delayed gastric emptying should be excluded. In addition, a mechanical cause of gastric outlet obstruction, such as postoperative adhesions, afferent or efferent loop obstruction, and internal herniation, must be ruled out. In patients with a functional gastric outlet obstruction and documented gastroparesis, pharmacotherapy is generally used. The agents most commonly used are prokinetic agents such as metoclopramide and erythromycin. In rare cases of persistent gastric atony refractory to medical management, subtotal or total gastrectomy may be required.

Roux Stasis Syndrome

Disordered motility of the Roux limb can result in stasis. Symptoms include vomiting, epigastric pain, and weight loss. Differentiation from gastric atony can be done with imaging showing a dilated Roux limb. Medical treatment is similar to gastric atony with either metoclopramide or erythromycin. In patients with Roux stasis syndrome and a large residual gastric remnant, surgical revision to create a smaller gastric remnant may be beneficial.

Postvagotomy Diarrhea

Episodic, significant diarrhea can result after vagotomy procedures. The mechanism is not fully understood but is thought to be partially related to rapid transit of unconjugated bile salts to the colon. It is most frequently seen after truncal vagotomy. Increased fiber intake and oral cholestyramine (a bile acid sequestrant) or an antidiarrheal agent are typically effective. Historically, surgery with a short antiperistaltic jejunal loop interposition was described, but this is not typically used today.

OTHER GASTRIC LESIONS

Atrophic Gastritis

Atrophic gastritis is a result of chronic inflammation leading to replacement of normal gastric glandular mucosa with connective tissue or intestinal-type cells. The two most common causes are *H. pylori* and autoimmune disease. Autoimmune gastritis can lead to pernicious anemia caused by vitamin B_{12} deficiency. On endoscopy, patients will have a pale mucosa. The updated Sydney protocol with biopsies from five specified sites in the stomach has high diagnostic accuracy for both atrophic gastritis and *H. pylori*. If *H. pylori* is diagnosed, it should be treated appropriately. Patients are recommended to undergo surveillance endoscopies after diagnosis of atrophic gastritis, as they are at increased risk of developing type 1 gastric neuroendocrine tumors and intestinal-type gastric adenocarcinoma, though the exact interval is not well defined.[37] Small gastric neuroendocrine tumors less than 1 cm can be managed with either endoscopic resection or active surveillance. Larger lesions should undergo EUS. Patients should undergo surgery if there is evidence of invasion beyond the submucosa, poor differentiation on biopsy, size greater than 2 cm, or positive margin after endoscopic resection.

Hypertrophic Gastritis (Ménétrier Disease)

Ménétrier disease is a rare disorder characterized by protein-losing gastropathy and massive gastric folds in the fundus and body of the stomach, giving the mucosa a cobblestone or cerebriform appearance. The antrum is typically spared in adults. Histologic examination reveals foveolar hyperplasia (expansion of surface mucus cells), with decreased or absent parietal cells. The condition is also associated with protein loss from the stomach, excessive mucus production, and decreased acid secretion. The pathogenesis of Ménétrier disease is poorly understood. It has been associated with CMV infection in children and *H. pylori* infection in adults. Increased levels of transforming growth factor-α have been noted in the gastric mucosa of patients with the disease, which can stimulate epithelial cell growth and inhibit gastric acid secretion. Patients often present with epigastric pain, vomiting, weight loss, decreased appetite, and peripheral edema caused by hypoalbuminemia. Typical gastric mucosal changes can be detected by radiographic or endoscopic examination. Biopsy should be performed to establish the diagnosis and to rule out malignant etiologies such as gastric adenocarcinoma or lymphoma. Patients with Ménétrier disease are at increased risk of gastric cancer, though the exact risk is not well known given the rarity of the disease. Medical treatment yields inconsistent results; however, some benefit has been shown with the use of acid suppression, octreotide, and CMV or *H. pylori* eradication. A small phase I trial of cetuximab (epidermal growth factor [EGF] receptor monoclonal antibody) showed clinical improvement in seven out of nine patients, with four achieving histologic remission.[38] Total gastrectomy should be considered in patients who continue to have massive protein loss despite optimal medical therapy and a high-protein diet or if they develop malignant changes.

Mallory-Weiss Tear

Mallory-Weiss tears are mucosal lacerations related to forceful vomiting, retching, coughing, or straining. These lacerations can cause acute upper GI bleeding from submucosal blood vessels. The most common risk factor is alcohol use. Patients present with hematemesis. Massive bleeding is more likely in patients with preexisting portal hypertension. Initial management is similar to other patients with acute upper GI bleed, with assessment of hemodynamic stability, PPI initiation, and antiemetics for nausea. Upper endoscopy is both diagnostic of Mallory-Weiss tears and therapeutic. Most patients with active bleeding can be treated with endoscopic methods, such as epinephrine injection, thermal coagulation, endoscopic band ligation, or endoscopic hemoclipping. Angiographic transarterial embolization may be useful in patients who have persistent or recurrent bleeding after endoscopy. Operative intervention is rarely needed. If surgery is required, an anterior gastrotomy is performed and the bleeding site is oversewn with several deep suture ligatures to reapproximate the gastric mucosa in an anatomic fashion.

Cameron Lesion

Cameron lesions are ulcers occurring as a result of a hiatal hernia and are seen as linear ulcers or erosions at the diaphragmatic impression. These are often discovered incidentally and rarely cause acute upper GI bleeding. They have been associated with chronic iron deficiency anemia. Acute bleeding is treated with standard endoscopic measures. Chronic iron deficiency anemia can initially be managed with PPI and iron repletion along with diagnostic workup to exclude other potential causes. Patients with persistent anemia with lack of another source and patients with symptoms of dysphagia should be evaluated for surgical hiatal hernia repair.

Dieulafoy Gastric Lesion

Bleeding from a gastric Dieulafoy lesion is caused by an abnormally large (1–3 mm), tortuous artery coursing through the submucosa without a primary ulcer. Erosion of the superficial mucosa overlying the artery occurs secondary to the pulsations of the large submucosal vessel. The artery is then exposed to the gastric contents, and further erosion and bleeding occur. The lesions generally occur near the GE junction along the lesser curvature. Dieulafoy lesions are more common in males, with associated comorbidities including cardiovascular disease, chronic kidney disease, and diabetes. The classic presentation of a patient with a Dieulafoy lesion is sudden onset of massive, painless hematemesis.

Detection and identification of the Dieulafoy lesion can be difficult. The diagnostic modality of choice is upper endoscopy, but because of the intermittent nature of the bleeding, repeat endoscopies may be needed in the absence of active bleeding. If the lesion can be identified endoscopically and is actively bleeding, endoscopic modalities such as bipolar electrocoagulation, heater probe thermocoagulation, injection sclerotherapy, or endoscopic hemoclipping can be applied. Angiography can be useful in cases in which endoscopy is unable to definitely identify the source of bleeding. Angiographic findings may include a tortuous ectatic artery in the distribution of the left gastric artery. Angiography can also show IV contrast extravasation in the setting of active bleeding. Embolization has been reported to control bleeding successfully in patients with Dieulafoy lesions. Surgery is rarely required and only indicated if patient fails less invasive interventions. Surgical management consists of gastric wedge resection to include the offending vessel, which can be facilitated by asking the endoscopist to tattoo the stomach when the lesion is identified or with intraoperative endoscopic localization.

Gastric Antral Vascular Ectasia

Gastric antral vascular ectasia (also referred to as GAVE or watermelon stomach) is an uncommon cause of acute upper GI bleeding, more often resulting in chronic iron deficiency anemia. The name watermelon stomach is derived from its endoscopic appearance of red stripes of ectatic mucosal vessels from the pylorus to the antrum. GAVE most commonly occurs in older females and is associated with cirrhosis and sclerosis. However, portal decompression has not been shown to decrease bleeding in GAVE. Endoscopic therapy is the preferred treatment modality for symptomatic patients. Antrectomy can be curative for patients who require intervention and fail more conservative measures.

Gastric Varices

Gastric varices are dilated submucosal veins commonly seen in patients with portal hypertension and cirrhosis, serving as a vascular shunt between the portal and systemic circulation. The prevalence of gastric varices is between 17% and 25% in patients with portal hypertension, and they are associated with more severe bleeding and higher mortality compared with the more common esophageal varices.[39] The Sarin classification characterizes two types: isolated gastric varices and GE varices.[40] Isolated gastric varices are further subclassified into type 1 varices, located in the fundus of the stomach, and type 2, isolated ectopic varices located anywhere in the stomach. GE varices are divided into type 1 along the lesser curvature of the stomach and type 2 along the greater curvature. Although GE varices are more common overall, isolated gastric varices are more prone to bleeding.

Gastric varices can develop secondary to portal hypertension, in conjunction with esophageal varices, or secondary to sinistral hypertension from splenic vein thrombosis. In generalized portal hypertension, the increased portal pressure is transmitted by the left gastric (coronary) vein to esophageal varices and by the short and posterior gastric veins to the fundic plexus and cardia veins. Isolated gastric varices tend to occur secondary to splenic vein thrombosis, which is most commonly the result of pancreatitis. Splenic blood flows retrograde through the short and posterior gastric veins into the varices and then through the coronary vein into the portal vein. Left-to-right retrograde flow through the gastroepiploic vein to the superior mesenteric vein can explain the development of ectopic varices in the stomach.

The incidence of bleeding from gastric varices has been reported to be between 3% and 30%. However, the incidence of bleeding can be much higher in patients with splenic vein thrombosis and fundic varices. Cardiofundal location, larger size of the varices, presence of discolored marks, and decompensated cirrhosis increase the risk for bleeding.[39]

Bleeding isolated gastric varices in the setting of splenic vein thrombosis are readily treated by splenectomy. Patients with bleeding gastric varices should have an imaging study to document splenic vein thrombosis before a splenectomy is performed because gastric varices are more often associated with generalized portal hypertension.

Acutely bleeding gastric varices in the setting of portal hypertension should be managed similarly to esophageal varices. The patient should have adequate vascular access and be volume-resuscitated, with attention paid to the correction of abnormal coagulation profiles. Temporary tamponade can be attempted with a Sengstaken-Blakemore tube, though this should be followed promptly by more definitive therapy to prevent mucosal erosion. Octreotide, a somatostatin analog, can be administered with bolus followed by continuous infusion. Prophylactic ceftriaxone should be administered if the patient is not allergic. When possible, CT with portal venous phase best defines the underlying vascular anatomy in patients with portal hypertension.

Management of gastric variceal bleeding should be done in a multidisciplinary setting. Endoscopy serves as the primary diagnostic and therapeutic tool and should be done urgently for actively bleeding varices; preprocedure erythromycin can be used to improve visualization. Endoscopic options to initially treat gastric variceal bleeding include sclerotherapy, band ligation, glue, or thrombin injection. A major problem with gastric varices after endoscopic treatment is rebleeding. The American Gastroenterological Association 2021 guidelines[39] for management of bleeding gastric varices recommend endoscopic cyanoacrylate injection in cases where definitive endoscopic therapy is favored; the guidelines also note that for lesser curvature gastric varices, band ligation can be definitive therapy. EUS can be used to improve the accuracy of cyanoacrylate injection, and this can be done with or without concomitant coil injection. When a gastrorenal shunt is present between the gastric varices and left renal vein, balloon-occluded retrograde transvenous obliteration can be performed with a sclerosant if local expertise is available. The major complication of this procedure is aggravation of esophageal varices secondary to an increase in portal pressure as a consequence of occluding the gastrorenal shunt. Repeat endoscopy should be performed within 48 hours to confirm obliteration of the gastric varices and evaluate for esophageal varix exacerbation. Transjugular intrahepatic portosystemic shunting (TIPS) can be effective in controlling gastric variceal hemorrhage that does not respond to endoscopic treatments or for patients with decompensated cirrhosis at high risk of failing endoscopic management. TIPS is more effective for lesser curvature gastric varices than cardiofundal greater curvature varices. Complications from TIPS include hepatic encephalopathy, liver failure, and heart failure.

Gastric Volvulus

Gastric volvulus is an uncommon condition. Torsion occurs along the stomach's long longitudinal axis (organoaxial) in approximately two-thirds of cases and along the short vertical axis (mesenteroaxial) in one-third of cases (Fig. 86.15). Rarely, a more complex form can occur with elements of both rotations. Rotation more than 180 degrees causes gastric outlet obstruction and can lead to ischemia, necrosis, and potentially perforation if left uncorrected. Primary gastric volvulus is caused by abnormalities of the gastric ligaments (i.e., gastrocolic, gastrohepatic). Secondary gastric volvulus is the result of other anatomic abnormalities, the most common being a paraesophageal hernia. In children, congenital defects such as the foramen of Bochdalek or diaphragmatic eventration are involved.

The sudden-onset severe upper abdominal pain, recurrent retching with limited vomiting, and the inability to pass an NG tube constitute the Borchardt triad for acute gastric volvulus. Plain films of the abdomen can reveal a spherical gas-filled viscus in the chest or upper abdomen with an air-fluid level. CT imaging will show a dilated stomach, a swirl sign of the esophagus and stomach, and possibly radiographic features of gastric necrosis such as pneumatosis or free air. CT also has the benefit of showing associated anatomic abnormalities (such as paraesophageal hernia) and excluding other more common causes of abdominal pain or lower chest pain. Chronic volvulus symptoms are intermittent and less severe. Imaging should be obtained during symptomatic episodes.

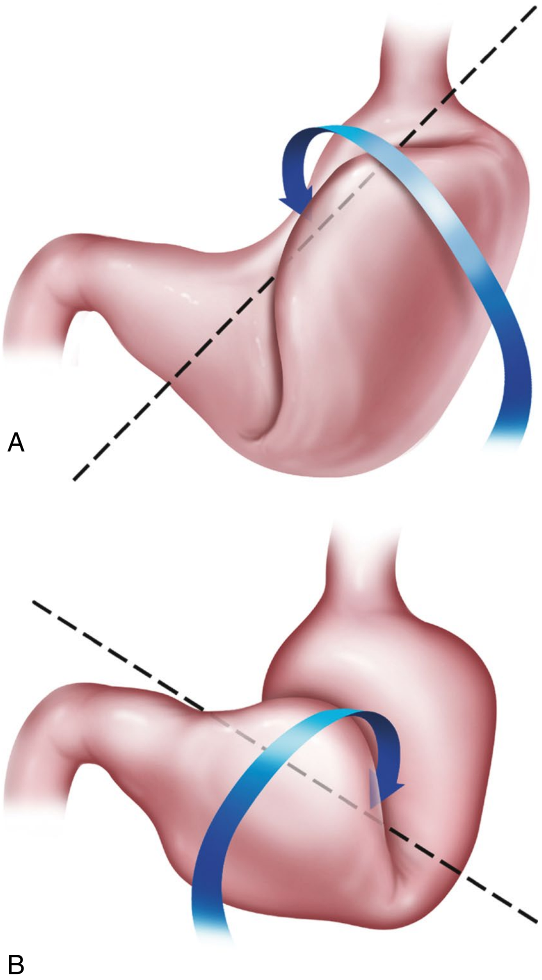

FIGURE 86.15 Torsion of the stomach along the longitudinal axis (organoaxial) (A) and along the short vertical axis (mesenteroaxial) (B). (From White RR, Jacobs DO. Volvulus of the stomach and small bowel. In: Yeo CJ, Dempsey DT, Klein AS, et al., eds. *Shackelford's Surgery of the Alimentary Tract*. 6th ed. Philadelphia: Saunders; 2007:1035-1040.)

Acute volvulus necessitates urgent treatment. IV fluids should be started and electrolyte abnormalities corrected. NG decompression should be performed immediately, which sometimes can detorse the stomach spontaneously. If bedside NG placement is unsuccessful, endoscopic decompression can be performed with care to limit insufflation. The distal stomach should be suctioned, the mucosa should be evaluated for ischemia, and an NG tube should be placed. Immediate surgical intervention is recommended for patients who fail NG or endoscopic decompression, have gastric perforation, or have severe sepsis or refractory hypotension. Patients that stabilize with decompression can delay definitive treatment until after appropriate preoperative workup.

If the patient is unstable, an urgent open operation is recommended. The stomach should be detorsed and then assessed for viability. Areas that remain ischemic should be resected. In the uncommon situation where the entire stomach is necrotic, a total gastrectomy can be performed with jejunostomy tube placement and esophagostomy with an elective reconstruction in the future. For stable patients with acceptable surgical risk, an open or laparoscopic approach can be undertaken. Primary gastric volvulus can be managed with suture gastropexy of the stomach to the anterior abdominal wall and is often combined with gastrostomy tube placement, though no technique is standardized. Secondary gastric volvulus should undergo repair of the anatomic defect rather than gastropexy alone when possible; typically, this involves repair of a paraoesophageal hernia. The diaphragmatic defect is repaired after the stomach hernia sac is reduced and the distal esophagus is mobilized; this is typically combined with a fundoplication. Patients with high surgical risk can instead undergo endoscopic detorsion with percutaneous endoscopic gastrostomy (PEG) tube placement to fixate the stomach. Two PEG tubes are used to prevent rotation. PEG tube placement can also be used as a temporizing measure in a hemodynamically unstable patient before definitive surgical repair.

Gastric Bezoars

A gastric bezoar is a collection of nondigestible materials found as a hard mass in the stomach. They are defined by their composition. The most common type of bezoar is composed of vegetable material, termed a *phytobezoar*. A subtype of phytobezoar, diospyrobezoars, are associated with ingestion of persimmon fruits, which contain a tannin that polymerizes in the acidic stomach environment. Bezoars can also contain hair (trichobezoar), medications (pharmacobezoars), or other substances.

Bezoars are most commonly found in patients who have underlying gastric dysmotility issues, such as prior gastric surgery, gastroparesis, or gastric outlet obstruction. Trichobezoars are often associated with psychiatric disorders. Impaired grinding mechanism of the stomach and migrating motor complexes have been implicated as pathogenic causes of bezoars, though some patients may have normal stomach function. Patients are often asymptomatic or have gradual symptom onset over years. The symptoms of gastric bezoars include early satiety, pain, nausea/vomiting, and weight loss. Gastric outlet obstruction from a bezoar is rare. Physical examination is usually unremarkable, although sometimes a large mass may be palpable. Abdominal radiographs or CT scans can show a bezoar as a mass or filling defect within the stomach; diagnosis is confirmed by upper endoscopy.

Initial management of symptomatic bezoars is attempted with chemical dissolution. This was first attempted in the 1950s using Adolph's Meat Tenderizer, which contains papain. There is currently a wide array of options, including soda (Coca-Cola being the most studied), cellulose, papain, and acetylcysteine; no randomized trials exist to suggest superiority of one dissolving agent compared with others. Of note, trichobezoars are typically resistant to chemical dissolution. Pharmacobezoars may require decontamination to prevent toxicity depending on the medication involved in the bezoar. If chemical dissolution is ineffective or contraindicated, endoscopic fragmentation with a water jet, forceps, or direct suction can be performed. The resulting fragments can either be removed via the endoscope, with an Ewald tube, or allowed to pass through the GI tract. Adjuvant prokinetics such as metoclopramide can be used in conjunction with either chemical dissolution or endoscopic therapy. Surgical removal is typically reserved for patients who fail more conservative management, present with a complication (i.e., gastric perforation or excessive bleeding), or if other therapies are contraindicated based on the bezoar's composition. Surgical removal of bezoars is typically done via an anterior gastrotomy. The stomach and small intestine should be fully evaluated for other bezoars at time of surgery.

This paper first summarizes current guidelines for Zollinger-Ellison syndrome diagnosis. It then highlights current issues with the standard diagnosis in assay reliability as well as ancillary testing availability and also addresses newer more commonly used modalities in clinical practice such as DOTATATE scans. A new proposed diagnostic algorithm is made based on their review.

Scally B, Emberson JR, Spata E, et al. Effects of gastroprotectant drugs for the prevention and treatment of peptic ulcer disease and its complications: a meta-analysis of randomised trials. *Lancet Gastroenterol Hepatol*. 2018;3(4):231-241.

This study examined the effects of three classes of gastroprotectants (PPIs, H_2 receptor antagonists, and prostaglandin analogs) for prevention and treatment of peptic ulcer disease by doing meta-analyses from randomized trials that either compared a gastroprotectant with a control or another medication. Larger proportional reductions in upper GI bleeding were seen with PPIs, and PPIs were the most effective in ulcer healing. In trials of patients with acute bleeding, PPIs had a larger protective effect than H_2 blockers for further bleeding and blood transfusion, but there was no significant difference in mortality.

GASTRIC ADENOCARCINOMA

Epidemiology

Incidence

Gastric cancer is one of the most common malignancies worldwide, with over 1 million cases per year and over 780,000 deaths per year.[1] The prevalence of gastric cancer is highest in Asia and Eastern Europe, with much lower rates in North America and Northern Europe. In the United States, there are an estimated 26,500 gastric cancer cases per year and 11,000 deaths per year. Within the United States, about 60% of gastric cancer cases and deaths occur in males; it is more common and has higher mortality in Blacks, Asian Americans, and Hispanics compared with Whites. Mortality rates also vary significantly throughout the world, with 5-year disease-specific survival over 80% in a Japanese national database compared with <50% in the United States; these differences are not fully explained by baseline differences in patient demographics and disease stage but may be related to differences in molecular subtypes of gastric cancer that predominate in different geographic regions.[2]

In addition, the prevalence of *Helicobacter pylori* infection (discussed later) explains much of the geographic variation in the global burden of gastric cancer. *H. pylori* infection can occur in infancy or childhood and causes chronic inflammation in the stomach that over years leads to cancer. The *H. pylori* seroprevalence rate varies markedly by country, ranging from 19% in Sweden to 88% in Nigeria; over half the world's population is infected.[3] Within the United States, the seroprevalence rate in Blacks and Hispanics is approximately 1.3 to 5.4 times higher than in Whites. It is thought that standards of living that provide better access to refrigeration and preservation of food and improved sanitation in industrialized countries have contributed to decreased *H. pylori* prevalence over time. Indeed, in the United States, gastric cancer was the leading cause of cancer deaths in the early 20th century but dropped sharply after 1930 with the establishment of the FDA and government-imposed standards on food preparation, sanitization, and preservation.[4]

In contrast to distal (noncardia) gastric cancers, which are principally associated with chronic *H. pylori* infection, cancers of the gastric cardia share similar risk factors with Barrett esophagus and esophageal adenocarcinoma, specifically obesity and gastroesophageal reflux disease. As such, the incidence of cardia gastric cancers has remained stable or increased in Western countries.[5] Alarmingly, like other GI cancers, young-onset noncardia gastric cancers in patients age 25 to 40 years have increased significantly since the 1970s; the risk factors that have led to this remain uncertain.[6]

Risk Factors

The major risk factors for gastric cancer are discussed here, including both environmental and genetic factors (Box 87.1).

H. pylori, *Epstein-Barr virus, and the microbiome.* Globally, chronic *H. pylori* infection is by far the most important risk factor for gastric cancer. *H. pylori* is associated with approximately 75% of all gastric cancer cases worldwide and is classified by the World Health Organization (WHO) International Agency for Research on Cancer (IARC) as a group 1 (definite) carcinogen.[7] As such, stomach cancer is the most common infection-related cancer. *H. pylori* seropositivity confers an approximately sixfold increased risk of developing gastric cancer; even after *H. pylori* eradication, an increased risk of gastric cancer persists.

H. pylori infection is associated with a variety of gastric phenotypes; the vast majority of *H. pylori*–infected individuals do not go on to develop gastric cancer. The most common phenotype is mild pangastritis with largely normal gastric acid secretion. Next most common is the duodenal ulcer phenotype, characterized by antral gastritis with high gastrin and high acid secretion. In contrast,

BOX 87.1 Risk Factors Associated With the Development of Stomach Cancer

Medical/Infectious

Helicobacter pylori and Epstein-Barr virus infection
Hereditary predisposition
Prior abdominal radiation
Atrophic gastritis
Adenomatous polyps
Prior gastric surgery
Obesity
Long-term proton pump inhibitor use

Nutritional

Salted meat or fish
High nitrate consumption
Low fresh fruit and vegetable consumption

Environmental

Lack of refrigeration
Contaminated drinking water (e.g., well water)
Smoking and alcohol

Social and Demographic

Low socioeconomic status
Male sex

gastric cancer is typically associated with a gastric body–predominant gastritis with multifocal gastric atrophy and decreased gastric acid secretion. These changes are induced by chronic inflammation caused by *H. pylori* infection and increase the risk of gastric cancer. The progression of chronic *H. pylori* infection to invasive cancer is believed to develop sequentially from nonatrophic gastritis, to atrophic gastritis, then to intestinal metaplasia, dysplasia, and adenocarcinoma. *H. pylori*–associated stomach cancer is almost always seen in the context of intestinal metaplasia.

The best-characterized *H. pylori* virulence factors are cytotoxin-associated gene A (*cag*A) and vacuolating cytotoxin A (*vac*A), which co-opt the host inflammatory response to promote oncogenesis; this is illustrated by the finding that high-risk *H. pylori* genotypes act synergistically with proinflammatory interleukin-1 gene cluster variants in patients to increase the risk of gastric cancer up to 87-fold.[8] Epidemiologically, *cag*A-positive isolates comprise a higher percentage of *H. pylori* strains in East Asian countries than in Western countries, and *cag*A gene variants originating in East Asia induce gastric cancer more efficiently compared with those from the West.[9]

Latent Epstein-Barr virus (EBV) infection is also associated with the development of gastric cancers. In these tumors, the integrated viral genome, and consequently transcribed viral messenger RNA (mRNA) and translated viral proteins, can be detected. EBV alters host gene expression within infected cells both by EBV-encoded microRNAs and by inducing hypermethylation of host DNA. EBV-associated tumors comprise a unique molecular subtype of gastric cancer, as discussed later.

Microbes other than *H. pylori* and EBV may also contribute to gastric cancer. Various studies have shown differences between the gastric microbiome in patients with gastric cancer compared with controls or in resident microbes obtained from gastric cancer tissue versus benign gastric tissue from the same patient. In particular, microbes that contribute to the production of nitrite and *N*-nitroso compounds (which are known to contribute to gastric carcinogenesis; see "Dietary Factors") may be more prevalent in the stomachs of patients with gastric cancer.[10] *H. pylori* may perturb the gastric microbiome by increasing gastric pH via urease production, allowing overgrowth of nitrite- and *N*-nitroso–producing bacteria. A similar pH-dependent mechanism may underly epidemiologic findings linking long-term proton pump inhibitor (PPI) use with increased risk of gastric cancer.[11] Based on the potential for adverse effects from long-term PPI use, deprescribing PPIs is recommended for patients without an ongoing indication for PPI use. Patients with persistent dyspepsia on PPI therapy warrant surveillance for and eradication of *H. pylori*.

Dietary factors. *N*-nitroso compounds, either derived directly from dietary sources or by endogenous production from nitrates and nitrites, are the major dietary contributors to gastric carcinogenesis. Smoked, cured, and preserved meats and other foods are the primary dietary sources of these compounds. Consistent with epidemiologic data linking smoking with an increased risk of gastric cancer, *N*-nitroso species are also present in cigarette smoke. Salted and pickled food intake is also associated with gastric cancer, possibly because of mucosal injury to the stomach. Fresh fruits and vegetables are dietary sources of ascorbic acid, an antioxidant that inhibits the conversion of nitrites to *N*-nitroso compounds. Accordingly, low intake of fresh fruits and vegetables is associated with increased risk of developing gastric cancer.

The interactions between the gastric microbiome and dietary factors are complex, but there is evidence for synergistic effects of *H. pylori* infection with smoking or high salt intake to promote gastric carcinogenesis. Alongside improvements in sanitation that have reduced *H. pylori* infection, the widespread introduction of refrigeration, by reducing reliance on other meat preservation methods and allowing for increased consumption of fresh fruits and vegetables, has likely contributed to decreased gastric cancer incidence in industrialized countries. In 2015, the WHO IARC classified processed meats as a group 1 carcinogen.

Hereditary risk factors. Hereditary diffuse gastric cancer (HDGC), classically resulting from a germline mutation in the gene encoding the cell adhesion and signaling molecule E-cadherin, *CDH1,* is associated with an increased risk of developing diffuse gastric cancer. The original estimates of lifetime risk of developing HDGC in individuals with germline *CDH1* mutation were 55% to 70% or greater.[12,13] However, this estimate of lifetime risk was subject to ascertainment bias, as most identified cases were derived from kindreds with high burden of HDGC among multiple family members. As additional kindreds with weaker phenotypic expression (lower penetrance) have been reported among individuals undergoing germline *CDH1* testing for conditions other than diffuse gastric cancer, the risk estimates for HDGC in the setting of germline *CDH1* mutation have declined. Currently, the lifetime risk of HDGC in individuals with germline *CDH1* mutation is estimated at 37% to 42% for males and 25% to 33% for females.[14,15] The risk of developing gastric cancer may vary in each family depending on how many gastric cancer cases have been found. Roberts *et al.* estimated the risk in families with three or more gastric cancer cases as 64% in males and 47% for females.[14] This risk decreased to 27% for males and 24% for females in families with two or fewer gastric cancer cases. Females with germline *CDH1* mutation also carry a 39% to 55% risk of developing lobular breast cancer.

Prophylactic total gastrectomy should be considered for medically fit individuals with germline *CDH1* mutation who are deemed to have a significant risk of gastric cancer, typically between the ages of 20 and 30 years. In the vast majority of cases, microscopic foci of early gastric cancer will be seen in the gastrectomy specimen. In patients who refuse or wish to delay gastrectomy, annual endoscopy with Cambridge protocol biopsies (targeted biopsies of all identified lesions plus at least 6 random biopsies from each of 5 different anatomic regions) or Bethesda protocol biopsies (targeted biopsies of all identified lesions plus at least 4 random biopsies from each of 22 different sites) are recommended. The targeted biopsies of suspected clinical cancers may be the most important aspect of surveillance endoscopies. Many, if not most, microscopic foci of early gastric cancer in *CDH1* individuals will never go on to become a clinically significant cancer. Because 90% or more of those with germline *CDH1* mutation will have one or more microscopic foci of early gastric cancer on prophylactic total gastrectomy,[16] the clinical significance of such foci on random biopsy is unclear. For patients with HDGC with uncertain risk of gastric cancer, such as those with *CDH1* variants of unknown significance and the more recently described pathogenic *CTNNA1* variants, annual surveillance with endoscopy and Cambridge or Bethesda protocol biopsies is also recommended.

Patients with HDGC are also at higher risk for lobular breast cancer, and annual surveillance with breast MRI is thus recommended beginning at age 30.[17] Lobular breast cancer often does not form a discrete mass or form microcalcifications, so the utility of mammogram is lower than that for infiltrating ductal carcinoma.[18] Bilateral risk-reducing mastectomies can also be considered.

Other germline genetic conditions associated with gastric cancer are listed in Table 87.1. Among these, in familial adenomatous polyposis (FAP), most patients will have fundic or body sessile polyps, with 40% of these polyps having some degree of dysplasia. These polyps, combined with the much higher frequency of potentially malignant duodenal polyps, warrant upper GI surveillance. Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS) is characterized by fundic gland polyposis of the gastric fundus and body, classically with >100 polyps carpeting the proximal stomach, which can progress to dysplasia and invasive cancer. Because of its rarity, there are no comprehensive guidelines for patients with GAPPS, but gastroscopy should be performed annually starting at age 15, and risk-reducing total gastrectomy should be considered starting in the third decade of life. Lynch syndrome predisposes to microsatellite-unstable malignancies, including stomach cancer. As discussed later, these are more amenable to treatment with immunotherapy than conventional cytotoxic chemotherapy. Upper GI screening with esophagogastroduodenoscopy (EGD) starting in the teenage years is recommended for patients with juvenile polyposis and Peutz-Jeghers syndromes.

Gastric polyps. Gastric polyps are identified in approximately 6% of gastroscopies in the United States and are usually asymptomatic. These comprise a variety of pathologic entities, including adenomas, fundic gland polyps, and hyperplastic polyps. All gastric polyps detected at endoscopy should be biopsied to determine malignancy risk and guide further management. Solitary polyps >1 cm in size should undergo complete polypectomy. In cases of multiple polyps, the largest should be removed endoscopically, if possible, and remaining polyps should be biopsied. In addition, normal antral and body mucosa should be biopsied to rule out atrophic gastritis and to diagnose *H. pylori*.

Adenomatous polyps often occur in the background of chronic or atrophic gastritis but also can occur in patients without preexisting gastritis and are most commonly found in the antrum. They can progress to atypia, dysplasia, and invasive carcinoma, with higher risk of invasive carcinoma correlating with increased size, villous contour, and degree of dysplasia. Complete endoscopic removal of gastric adenomas should be performed. In addition to the local risk of progression to invasive cancer, the risk of synchronous or metachronous gastric cancer is elevated in patients with an adenomatous polyp; as such, thorough endoscopic evaluation and endoscopic follow-up are mandatory after resection of gastric adenomas.

Hyperplastic polyps most commonly occur in the setting of chronic atrophic gastritis, resulting from chronic inflammatory conditions, including *H. pylori* infections and pernicious anemia. These can progress to carcinoma in a stepwise process via dysplasia. Foci of dysplasia are found in approximately 1% to 20% of hyperplastic polyps. The risk of malignancy is higher in pedunculated polyps and those >1 cm in size.

Fundic gland polyps are benign lesions that can occur sporadically, but are also associated with long-term PPI use and can be seen in adenomatous polyposis coli (APC), GAPPS, and *MUTYH*-associated polyposis syndromes, as discussed earlier. They occur in one-third of patients by 1 year of PPI treatment, and resolution of fundic gland polyps after cessation of PPIs has been described. Dysplasia is most common in patients with fundic gland polyps resulting from hereditary cancer syndromes and occurs only rarely in patients whose polyps result from PPI therapy. PPI-associated fundic gland polyps do not require excision, regular surveillance, or cessation of therapy. The finding of numerous fundic gland polyps or fundic gland polyps harboring

TABLE 87.1 Hereditary Cancer Syndromes Associated With Stomach Cancer

GENETIC LOCI	SYNDROME	GASTRIC CANCER RISK	OTHER CANCER RISKS
CDH1	Hereditary diffuse gastric cancer (HDGC)	Up to 70%	Lobular breast
CTNNA1	HDGC	Up to 57%	Lobular breast
STK11	Peutz-Jeghers syndrome	29%	Breast, GI, pancreas, ovarian, lung, GYN
SMAD4, BMPR1A	Juvenile polyposis	21%	Colon, pancreas, small bowel
MLH1, MSH2, MSH6, PMS2	Lynch syndrome	1%–13%	Colon, ovarian, uterine, urinary tract, other
APC	Familial adenomatous polyposis	1%–2%	Colon, duodenum, thyroid
APC promoter 1B	Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS)	12%–25%	Unknown, possibly colon
MUTYH	*MUTYH*-associated polyposis	2%	Colon, duodenal, ovarian, bladder, skin

Adapted from Slavin TP, Weitzel JN, Neuhausen SL, Schrader KA, Oliveira C, Karam R. Genetics of gastric cancer: what do we know about the genetic risks? *Transl Gastroenterol Hepatol.* 2019;4:55.

dysplasia in a patient under age 40 should prompt workup for cancer-polyposis syndromes, including colonoscopy.

Other risk factors. Patients with pernicious anemia are at increased risk for developing gastric cancer. Achlorhydria is the defining feature of this condition; it occurs when chief and parietal cells are destroyed by an autoimmune reaction. Obesity was determined by the IARC to be a risk factor for gastric cardia cancers.[19] Smoking is associated with an approximately 1.5-fold increase in gastric cancer risk. Prior abdominal irradiation, most commonly after testicular cancer or Hodgkin lymphoma, increases gastric cancer risk.

Pathology

Gross and Histologic Classification

Borrman classification. Numerous pathologic classification schemes of gastric cancer have been proposed. The Borrmann classification system was developed in 1926 based on the gross appearance of advanced tumors. This system divides gastric adenocarcinoma into four types: type I for polypoid, type II for fungating, type III for ulcerating, and type IV for diffusely infiltrating growths (also referred to as *linitis plastica in signet ring cell carcinoma*). This classifier may be useful for the description of endoscopic findings, but its prognostic significance is limited.

Lauren classification. In 1965, Lauren proposed classifying gastric adenocarcinoma based on histology into intestinal or diffuse types; subsequently, others have included mixed-type tumors in this scheme. The intestinal variant is more well differentiated and typically arises in the setting of a recognizable precancerous condition, such as gastric atrophy or intestinal metaplasia. Males are more commonly affected than females, and the incidence of intestinal-type gastric adenocarcinoma increases with age. These cancers tend to form glands. The intestinal type is also the dominant histology in areas in which gastric cancer is epidemic, suggesting an environmental cause. Local rates of *H. pylori* prevalence likely play a large part in this increased environmental risk, as infection has been linked to the development of intestinal variant gastric cancer specifically. The diffuse form of gastric adenocarcinoma consists of tiny clusters of small, uniform signet ring cells; is poorly differentiated; and lacks glands. It tends to spread submucosally, with early metastatic spread via transmural extension and lymphatic invasion. It is generally not associated with chronic gastritis, is equally frequent in both sexes, and affects a slightly younger age group. The diffuse form also has an association with blood type A. Diffuse-type tumors often metastasize to the peritoneal cavity as carcinomatosis, whereas intestinal-type tumors more frequently metastasize to the liver.[20] The prognosis for diffuse-type tumors is less favorable than for patients with intestinal-type tumors. Mixed-type gastric adenocarcinoma is characterized by both intestinal and diffuse components and has an intermediate to poor prognosis.[21] The combination of Lauren classification with tumor location, known as the *modified Lauren classification,* is used to classify tumors as diffuse, proximal nondiffuse, or distal nondiffuse.[22] Modified Lauren classification is a better predictor of survival than histologic classification alone, with distal nondiffuse cancers having the best prognosis and diffuse cancers having the worst prognosis.[23]

World Health Organization classification. The WHO classifies gastric cancer as tubular, papillary, mucinous, poorly cohesive (including signet ring cell carcinoma), or mixed carcinomas based on the microscopic morphology of the tumor. Tubular and papillary carcinomas generally correspond to Lauren intestinal type, whereas poorly cohesive carcinomas, including signet ring cell tumors, correspond to diffuse type. Although the WHO system provides a standardized framework that encompasses uncommon histologic variants, it does not add significant prognostic or therapeutic clinical utility.

Molecular Subtypes

Stomach cancers exhibit significant heterogeneity in terms of their genetic alterations. The molecular drivers of gastric cancer include mutations that are common across a variety of cancers, such as the tumor suppressor gene *TP53* and the oncogene *KRAS*. Other important pathways that can be dysregulated in oncogenesis include cell adhesion (most commonly via *CDH1* mutations in diffuse-type and signet ring cell gastric cancer), cell cycle, apoptosis, microsatellite instability (MSI), and epigenetic changes. An important molecular marker is HER2 (encoded by the *ERBB2* gene), as its amplification or overexpression predicts response to HER2 inhibition. To address the challenges presented by the genetic heterogeneity of gastric cancer, mRNA and protein expression-based classification systems have been proposed.

The Cancer Genome Atlas molecular classification. Based on transcriptomic and proteomic profiles of gastric cancers from The Cancer Genome Atlas (TCGA), four molecular subtypes of gastric cancer were proposed in 2014: EBV-positive, MSI, genomically stable (GS), and chromosomal instability (CIN).[24] These subtypes correlate, albeit imperfectly, with previously known gastric cancer characteristics. CIN tumors generally exhibit intestinal-type histology and have a high prevalence of *TP53*-inactivating mutations, whereas GS tumors are enriched for diffuse-type histology and accordingly have a higher prevalence of somatic *CDH1* mutations. TCGA-based molecular classification alone is not a strong prognostic indicator, but it can be used to predict response to therapy. As discussed later, MSI tumors are generally unresponsive to cytotoxic chemotherapy, but MSI and EBV tumors show greater response to immunotherapy.

Asian Cancer Research Group molecular classification. In 2015, using gene expression data from the Asian Cancer Research Group (ACRG), another classification scheme was proposed, dividing gastric cancers into four molecular subtypes: Microsatellite-unstable (MSI), microsatellite stable/TP53 active (MSS/TP53+), microsatellite stable/TP53 inactive (MSS/TP53–), and microsatellite stable/epithelial-mesenchymal transition (MSS/EMT). Compared with the TCGA-based molecular classification, MSI subtypes are generally concordant and MSS/EMT correlates with the GS subtype, but these classification schemes have significant heterogeneity. This may be attributable to different baseline characteristics in the cohorts used to derive the molecular signatures in each study.[25]

Diagnosis and Workup

Screening

Gastric cancer screening has been implemented for the general population in countries with high incidence, including Japan, South Korea, Venezuela, and Chile, via upper endoscopy or barium radiography. For example, the South Korean national healthcare system covers screening upper endoscopies every 2 years beginning at age 40. Upper endoscopy is more invasive and costly than barium radiography, but it is more sensitive. Recommendations for modality, interval, and age of screening vary between countries and have not been directly compared. In contrast to universal screening, selective screening of high-risk patients should be considered in areas with low gastric cancer incidence. Screening and surveillance in patients with hereditary cancer syndromes is discussed earlier.

Patients with extensive gastric atrophy or gastric intestinal metaplasia should undergo endoscopic surveillance every 1 to 3 years.

Signs and Symptoms

Patients with gastric cancer tend to have vague and nonspecific symptoms, most commonly weight loss and persistent abdominal pain. As a result, stomach cancers are frequently diagnosed at advanced stages. With tumor growth, gastric cancer may cause dysphagia when located near the gastroesophageal (GE) junction or gastric outlet obstruction when located in the distal stomach. GI bleeding is also common, with 40% of patients having some degree of anemia.

A complete history and physical examination should be performed, with special attention to any evidence of advanced disease, including metastatic nodal disease. Presence of supraclavicular (Virchow node), axillary (Irish node), or periumbilical (Sister Mary Joseph node) adenopathy should be assessed as well as any evidence of intraabdominal metastases such as hepatomegaly, jaundice, or ascites. Drop metastases to the ovaries (Krukenberg tumor) may be detectable on pelvic examination, and peritoneal metastases can be felt as a firm shelf (Blumer shelf) on rectal examination. Complete blood count, chemistry panel including liver function tests, and coagulation studies should be performed. The tumor markers CEA and CA19-9 are sometimes elevated.

Staging

The most widely used staging system is the American Joint Committee on Cancer (AJCC) TNM staging system. This system is based on the depth of tumor invasion (T), number of involved lymph nodes (N), and presence or absence of metastatic disease (M), with the 8th edition published in 2017 (Table 87.2). Before 1997, N stage was determined by the anatomic location of the nodes with respect to the primary tumor, rather than the absolute number of nodes. The current system determines N stage based on the number of positive nodes, which has greater prognostic value than the location of positive nodes, with the caveat that a minimum of 16 lymph nodes must be evaluated for accurate staging.[26] The current AJCC staging system also includes a separate staging section for patients who received

TABLE 87.2 Tumor, Node, Metastasis Classification of Carcinoma of the Stomach

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
TO	No evidence of primary tumor
Tis	Carcinoma in situ; intraepithelial tumor without invasion of the lamina propria, high-grade dysplasia
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
Tla	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria[a]
T3	Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures[b]
T4	Tumor invades serosa (visceral peritoneum) or adjacent structures[b]
T4a	Tumor invades serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis[c]
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in 7 or more regional lymph nodes
N3a	Metastasis in 7–15 regional lymph nodes
N3h	Metastasis in 16 or more regional lymph nodes
Distant Metastasis (M)	
MD	No distant metastasis
MI	Distant metastasis

[a] A tumor may penetrate the muscularis propria with extension into the gastrocolic or gastrohepatic ligaments or into the greater or lesser omentum without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified T4.

[b] The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.

[c] A designation of pN0 should be used if all examined lymph nodes are negative, regardless of the total number removed and examined.

From Amin MB, Edge SB, Greene FL, et al. *AJCC Cancer Staging Manual*. 8th ed. New York: Springer International Publishing; 2017.

neoadjuvant therapy. Other parameters in addition to TNM have been proposed, including location of the primary tumor (as in the Japanese Research Society for Gastric Cancer system) or lymph node ratio (the percentage of all harvested lymph nodes that are positive), because these may provide additional prognostic information.

The Siewert classification is used for adenocarcinomas of the GE junction, defined as tumors with an epicenter with 5 cm proximal or distal to the GE junction. There are three Siewert types: Type I tumors are tumors of the distal esophagus, centered within 1 to 5 cm above the GE junction; type II tumors have a tumor center located from 1 cm above the GE junction to 2 cm below; type III tumors are centered between 2 and 5 cm caudad to the GE junction. In general, Siewert type I tumors are staged using the esophageal cancer staging system and treated similarly to esophageal adenocarcinoma, whereas type III tumors can be staged and treated according to the guidelines for gastric adenocarcinoma described here; these distinctions are reflected in the current AJCC TNM staging guidelines. Current AJCC guidelines stage Siewert II tumors as esophageal cancers. However, there are studies showing these tumors are better staged as gastric cancer.[27,28]

Although not part of the formal AJCC staging system, R status, first described by Hermanek in 1994, is used to describe tumor status after resection and is important for determining the adequacy of surgery. R0 describes a microscopically margin-negative resection in which no gross or microscopic tumor remains in the tumor bed. R1 indicates removal of all macroscopic disease, but microscopic margins are positive for tumor. R2 indicates gross residual disease. Because the extent of resection can influence survival, some include this R designation to complement the TNM system. R0 resection is associated with improved overall survival (OS) in patients with early stage disease, but not in patients with locally advanced disease.[29]

Staging Workup

The goals of preoperative staging are to gain information on prognosis, to counsel the patient effectively, and to determine the extent of disease to decide the most appropriate course of therapy. All patients should undergo endoscopic biopsy to confirm the diagnosis and CT imaging of the chest, abdomen, and pelvis. Based on these evaluations, if early disease (cT1-2/N0) is suspected (small tumor and normal gastric distensibility on endoscopy; no visible primary tumor, ascites, or metastatic disease on CT), endoscopic ultrasound (EUS) is the next step for locoregional staging. However, if locally advanced (cT3-4 and/or N+) or metastatic disease is suspected, PET/CT imaging and diagnostic laparoscopy are indicated (Fig. 87.1). PET/CT and laparoscopy will identify metastatic disease in about 25% to 30% of patients deemed to have locally advanced disease based on CT scans.

Endoscopy and biopsy. Flexible endoscopy is an essential tool for the diagnosis of gastric cancer. It allows visualization of the tumor, provides tissue for pathologic diagnosis, and can help treat patients with obstruction or bleeding (Fig. 87.2). The location of the tumor in the stomach and, in particular, its relation to the GE junction for proximal lesions (including Siewert classification) should be documented. On initial diagnostic endoscopy, if a suspicious mass or ulcer is encountered in the stomach, it is essential to obtain adequate tissue to confirm the correct diagnosis histologically. Current National Comprehensive Cancer Network (NCCN) guidelines recommend harvesting six to eight biopsy specimens from different areas of the lesion in order to maximize the diagnostic yield.[30] Small lesions (<2 cm in diameter) without ulceration can be resected endoscopically at the time of initial diagnostic endoscopy.[31] This resection can provide a more complete specimen to aid the pathologist in obtaining an accurate diagnosis and can potentially be curative for early stage cancers. Techniques of endoscopic resection are discussed in detail later.

In addition to histologic assessment, tumors should be assessed for MSI or MMR protein expression status, HER2, programmed cell death ligand 1 (PD-L1), and EBV status. *H. pylori* testing and treatment should also be performed when the clinical picture is consistent with *H. pylori*–associated disease.

Computed tomography. All patients with gastric cancer should undergo CT of the chest, abdomen, and pelvis with IV contrast to evaluate the primary tumor and lymph nodes and to rule out metastatic disease. CT has limited accuracy for locoregional staging, with 43% to 82% accuracy in measuring depth of invasion and 78% accuracy in detecting local lymph node involvement.[32] As such, EUS should be performed for local staging if early stage disease is suspected or if early versus locally advanced disease needs to be determined.

Endoscopic ultrasound. EUS provides the most accurate assessment of depth of tumor invasion and can also assess perigastric lymph node involvement. This test is only clinically useful in patients suspected of having early stage disease who are being considered for up-front surgical resection. EUS is performed using a flexible endoscope with a 7.5- to 12-MHz ultrasound transducer. The stomach is filled with water to provide an acoustic window, and the stomach wall is visualized as five alternating hypoechoic and hyperechoic layers. The mucosa and submucosa represent the first three layers (T1). The fourth layer is the muscularis propria, invasion of which signifies a T2 tumor. Expansion of the tumor beyond the muscularis propria causing an irregular border correlates with expansion into the subserosa, or a T3 tumor. The serosa is the fifth layer, and loss of this bright line correlates with penetration through it, indicating a T4a tumor. Direct invasion of surrounding structures, including named vessels, indicates a T4b tumor. Nodes are evaluated based on their size and ultrasound appearance and can additionally be sampled using fine-needle aspiration (FNA) under EUS guidance. FNA can also be performed if ascites is present to evaluate for peritoneal spread. The overall accuracy of EUS is highly operator dependent and ranges from 57% to 88% for T stage and 30% to 90% for N stage. There is improved accuracy when T and N stages are grouped together to differentiate high-risk versus low-risk disease, defined by the presence of any subserosal or serosal (T3/T4) involvement or any nodal disease (>N0). A Cochrane meta-analysis found that the summary sensitivity and specificity of EUS for discriminating T1/T2 versus T3/T4 disease were 86% and 90%, respectively.[32] The sensitivity and specificity for nodal involvement were 83% and 67%, respectively. As such, EUS is reliable in identifying patients with locally advanced tumors who should receive neoadjuvant treatment, as discussed later. However, given the importance of T staging to predict lymph node status in early stage gastric cancer, accurate EUS assessment is increasingly important to guide treatment decisions regarding neoadjuvant therapy and consideration for endoscopic resection (see later). A collaborative relationship with a skilled and experienced endoscopist is therefore critical for the surgeon who treats gastric cancer.

Positron emission tomography. Combined PET/CT is more accurate in preoperative staging (68%) than either PET (47%) or CT (53%) alone. It is particularly useful in patients with locally advanced disease and patients being considered for neoadjuvant therapy to better assess for occult metastasis.[33] Further, patients with PET-avid tumors can be monitored for a response to neoadjuvant therapy, which strongly correlates with survival. Based on these data, the NCCN guidelines recommend considering PET/CT as part of staging for patients with greater than T1 disease without evidence of metastatic disease on initial CT. However, the sensitivity of PET/CT for detecting peritoneal metastases is poor.

Staging laparoscopy. Patients with T3/4 or N+ tumors should undergo diagnostic laparoscopy with peritoneal washing before resection or neoadjuvant treatment. In contrast to imaging, laparoscopy has a >90% accuracy in detecting peritoneal metastasis.[34] Depending on the cohort, diagnostic laparoscopy in these patients detects occult peritoneal metastasis in <10% to over 50% of patients. Accordingly, diagnostic laparoscopy may change management in a significant number of patients. In addition to biopsies of any suspicious lesions, cytologic examination should be performed on any ascites as well as peritoneal washings from the left upper quadrant, right upper quadrant, and pelvis. Positive peritoneal cytology is associated with short OS and is correlated with higher T and N stages.[35] Based on NCCN guidelines, positive peritoneal cytology is defined as pM1 disease.

If up-front resection is planned, diagnostic laparoscopy should be performed before proceeding with resection; this can be done in a single-stage procedure. If neoadjuvant chemotherapy is planned, diagnostic laparoscopy should occur before initiating chemotherapy. Repeat diagnostic laparoscopy after neoadjuvant therapy is not currently part of the NCCN response assessment algorithm but should be considered in patients with evidence of disease progression on preoperative chemotherapy. A proportion of patients with initially positive peritoneal cytology will convert to negative cytology after neoadjuvant therapy; this group has an improved prognosis compared with those with persistently positive cytology, but the role of surgery after conversion to negative cytology is not well defined.[36]

Treatment

Surgical Therapy

For resectable gastric cancers, surgical excision remains the cornerstone of curative-intent treatment. Once staging is complete and resectability is established, the options are (1) endoscopic resection, (2) up-front resection with partial or total gastrectomy, or (3) preoperative chemotherapy or chemoradiation. Patient selection and technical aspects of resection options, including minimally invasive techniques and extent of lymphadenectomy, are discussed here. Patient selection for chemotherapy and radiation therapy and decision-making about treatment sequencing are discussed later.

Endoscopic resection. For select patients with early gastric cancer, endoscopic tumor resection can be performed for curative intent with adequate oncologic outcomes. The two primary modalities are endoscopic mucosal resection (EMR; Fig. 87.3) and endoscopic submucosal dissection (ESD; Fig. 87.4). The most significant advantage of endoscopic resection is avoiding the need for gastrectomy. The major disadvantages are risk of incomplete resection and unrecognized lymph node metastases. The standard criteria for endoscopic resection consideration are intestinal type adenocarcinoma, tumor confined to the mucosa, absence of lymphovascular invasion, nonulcerated, and less than 2 cm in diameter (Box 87.2). Meta-analyses have shown that endoscopic resection is associated with higher rates of incomplete resection and recurrence but no differences in 5-year OS compared with conventional resection.[37] Some East Asian guidelines now suggest expanded indications for endoscopically resectable tumors >2 cm without ulceration and those ≤3 cm with ulceration that otherwise meet standard criteria and for nonintestinal and poorly differentiated tumors <2 cm confined to the mucosa without ulceration (Fig. 87.5). Risk of lymph node involvement in patients meeting expanded criteria is higher at 0.7% compared with 0.2% among patients meeting standard criteria, and expanded criteria have not been widely adopted in Western centers.[38]

BOX 87.2 Standard Criteria for Endoscopic Resection of Gastric Adenocarcinoma

Intestinal-type adenocarcinoma
Tumor confined to the mucosa (Tis or T1a)
Absence of lymphovascular invasion
Nonulcerated tumor
Less than 2 cm in diameter

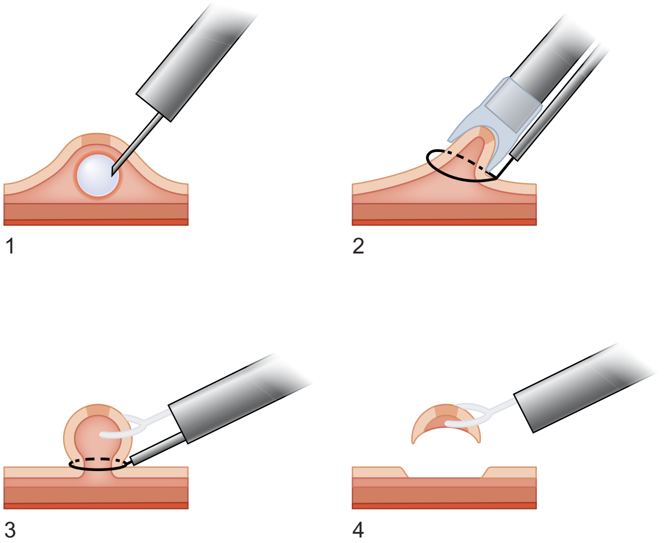

FIGURE 87.3 Endoscopic mucosal resection by strip biopsy. Saline is injected into the submucosal layer, and the area is elevated. *(1)* The top of the mound is pulled upward with forceps, and the snare is placed at the base of the lesion *(2 and 3)*. Electrosurgical current is applied through the snare to resect the mucosa, and the lesion is removed *(4)*. (From Tanabe S, Koizumi W, Kokotou M, et al. Usefulness of endoscopic aspiration mucosectomy as compared with strip biopsy for the treatment of gastric mucosal cancer. *Gastrointest Endosc.* 1990;50:819-822.)

EMR involves elevating the tumor using a saline injection, encircling the affected mucosa using a snare device or suction cap, and then excising it with electrocautery. Perforation rates are low, and bleeding rates are approximately 15%; these can generally be controlled endoscopically without the need for further intervention. En bloc resection is preferred, as piecemeal resection is associated with an increased risk of recurrence. Patients with positive lateral margins can be considered for repeat endoscopic therapy or close surveillance. Patients with positive vertical margins, lymphovascular invasion, or submucosal invasion should be referred for gastrectomy with lymphadenectomy

ESD is mostly used in East Asia and allows for resection of larger tumors and those with limited submucosal involvement. This technique begins by marking the borders of the lesion using electrocautery. A submucosal injection of epinephrine with indigo carmine hydrodissects the lesion, and an insulation-tipped knife is used to remove the lesion by dissecting a submucosal plane deep to the tumor and removing it en bloc. Any bleeding is controlled with electrocautery. ESD is more technically challenging than EMR, and there is a higher risk of perforation with ESD compared with EMR.

Extent of resection. Complete resection of a gastric tumor with a wide margin of normal stomach remains the standard of care for resection with curative intent. Patients without metastatic disease or invasion of unresectable vascular structures such as the aorta, celiac axis, or common hepatic artery are candidates for curative resection. The extent of resection depends on the location of the tumor in the stomach and size of the tumor. For T4 tumors, any organ with invasion should be removed en bloc with the gastrectomy specimen to achieve a curative resection.

For cancers of the distal stomach, including the body and antrum, a distal gastrectomy is the appropriate operation. The proximal stomach is transected with a margin of at least 2 cm for cT1 tumors, at least 3 cm for cT2-T4 tumors with noninfiltrative margins, and at least 5 cm for cT2-T4 tumors with infiltrative margins. Frozen section analysis on any close proximal and/or distal margin should be performed before reconstruction, and, if positive, a wider excision should be performed when possible.

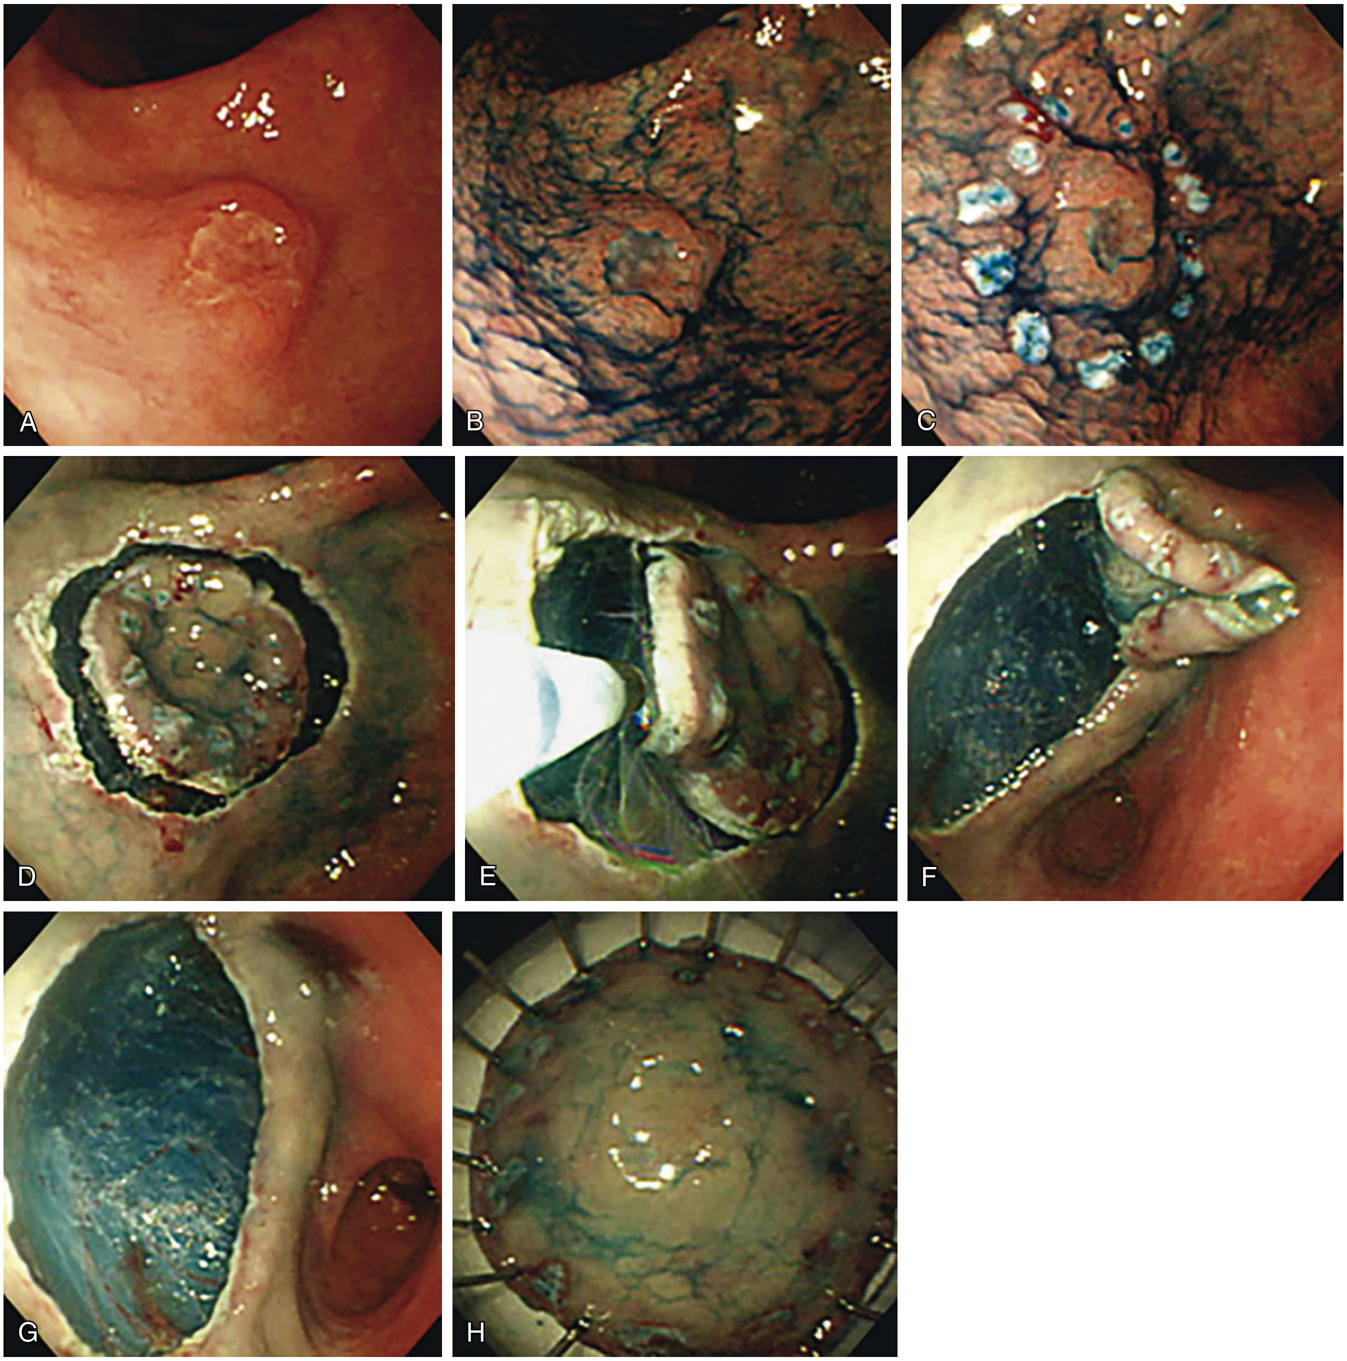

FIGURE 87.4 Procedure of endoscopic submucosal dissection. (A) A type IIA + IIC early gastric cancer was located at the lesser curvature side of the antrum. (B) Indigo carmine dye was sprayed around the lesion to define the margin accurately. (C) Marking dots were made circumferentially at approximately 5 mm lateral to the margin of the lesion. (D) After a submucosal injection of saline with epinephrine mixed with indigo carmine, a circumferential mucosal incision was performed outside the marking dots to separate the lesion from the surrounding nonneoplastic mucosa. (E–F) After an additional submucosal injection, the submucosal connective tissue just beneath the lesion was directly dissected using an electrosurgical knife instead of using a snare. (G) The lesion was completely resected, and the consequent artificial ulcer was seen. (H) The resected specimen with a central early gastric cancer. (From Min BH, Lee JH, Kim JJ, et al. Clinical outcomes of endoscopic sub-mucosal dissection [ESD] for treating early gastric cancer: comparison with endoscopic mucosal resection after circumferential precutting. The choice of reconstruction depends on the remnant anatomy with consideration of postgastrectomy physiology, although a Roux-en-Y reconstruction has been shown to result in less remnant gastritis and bile reflux esophagitis and improved quality of life at 1 year compared with Billroth reconstruction.[39]

In East Asian countries, where early gastric cancer is more common, a pylorus-preserving segmental gastrectomy can be performed for cT1N0M0 disease for cancers in the middle third of the stomach at least 5 cm from the pylorus. A Korean randomized controlled trial (RCT), the KLASS-04 trial, found no difference in overall complication rate with pylorus preservation; however, there was a 7% rate of pyloric stenosis requiring endoscopic intervention.[40] Antral cuff length in the pylorus preservation group averaged 4 cm. For early gastric cancers, the oncologic outcomes were similar between pylorus-preserving segmental gastrectomy and distal gastrectomy, with the former having lower rates of dumping syndrome, bile reflux, and malnutrition.

For proximal lesions of the fundus or cardia, a total gastrectomy with a Roux-en-Y esophagojejunostomy and proximal gastrectomy are equivalent from an oncologic perspective. The advantages of proximal gastrectomy include the preservation of the reservoir function and intrinsic factor production of the remnant distal stomach, pylorus preservation preventing reflux of duodenal contents, and decreased rate of dumping syndrome. On the other hand, additional care must be taken to ensure adequate lymph node harvest with proximal gastrectomy, and the incidence of anastomotic complications and reflux esophagitis may be higher with proximal esophagectomy depending on the method of reconstruction. Common reconstruction techniques after proximal gastrectomy include jejunal interposition, esophagogastrostomy, and double tract reconstruction consisting of three anastomoses: esophagojejunostomy, gastrojejunostomy, and jejunojejunostomy (Fig. 87.6). A Korean RCT, the KLASS-05 trial, compared laparoscopic total gastrectomy with laparoscopic proximal gastrectomy with double-tract reconstruction for early upper gastric cancer and showed similar perioperative morbidity without a significant difference in anastomotic complications and decreased vitamin B_{12} supplementation requirements in the double-tract reconstruction arm.[41]

As discussed earlier, Siewert type III GE junction tumors are treated as gastric cancers, whereas type I tumors are staged and

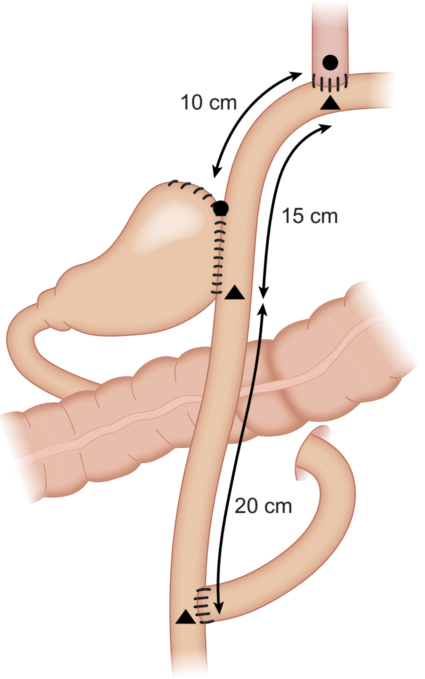

FIGURE 87.6 Schematic of double-tract reconstruction after proximal gastrectomy. (Adapted from Jung DH, Lee Y, Kim DW, et al. Laparoscopic proximal gastrectomy with double tract reconstruction is superior to laparoscopic total gastrectomy for proximal early gastric cancer. *Surg Endosc.* 2017;31[10]:3961-3969.)

treated according to esophageal cancer protocols. The approach to Siewert type II tumors remains controversial. A Japanese RCT assigned patients with proximal gastric cancer and esophageal invasion of ≤3 cm to a total gastrectomy either via abdominal approach with transhiatal resection of the lower esophagus or via left thoracic and abdominal approach with lower esophageal resection via the thorax. A total of 167 patients were randomized (82 to the transhiatal approach and 85 to the thoracoabdominal approach) before interim analysis determined that the thoracoabdominal approach does not improve survival but does confer increased morbidity (including 3 perioperative deaths in the thoracoabdominal arm compared with 0 in the transhiatal arm). A Dutch RCT compared transhiatal with transthoracic esophagectomy in 220 patients with either type I or type II GE junction tumors and found no significant survival benefit to either approach, but it did find increased perioperative morbidity in the transthoracic arm. A recent meta-analysis of 11 studies comparing esophagectomy with total gastrectomy, which included over 18,000 patients with Siewert type II GE junction tumors, showed decreased 30-day mortality and improved OS at 1, 3, and 5 years for patients undergoing total gastrectomy.[42] The ongoing CARDIA trial will compare transthoracic esophagectomy with transhiatal extended gastrectomy for Siewert type II tumors. Based on the current evidence, for Siewert type II tumors with esophageal extension of 2 to 3 cm or less, gastrectomy via the abdominal approach with transhiatal resection of the lower esophagus is oncologically appropriate and is associated with fewer surgical complications compared with transthoracic resection.

Extent of lymphadenectomy. The stomach has a rich supply of lymphatics (Fig. 87.7). Number of positive lymph nodes correlates

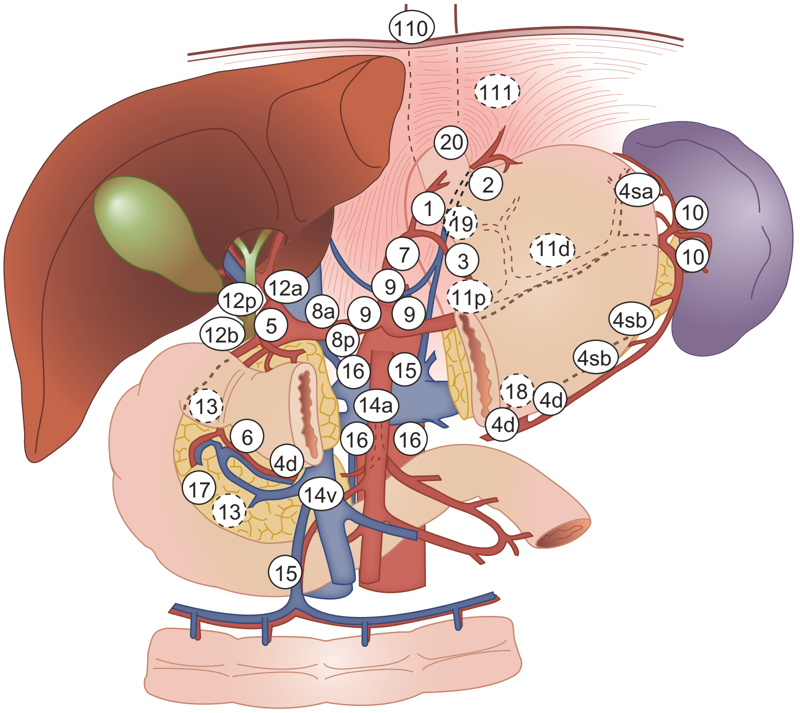

FIGURE 87.7 Lymph node station numbers as defined by the Japanese Gastric Cancer Association. (From Japanese Gastric Cancer Association. Japanese Classification of Gastric Carcinoma, 2nd English edition. *Gastric Cancer.* 1998:1:10-24.)

with survival in gastric cancer (Table 87.3). The extent of lymphadenectomy for gastric adenocarcinoma has been debated extensively. Historically, lymphadenectomy for gastric adenocarcinoma was defined by, and is still often discussed in terms of, the location of the nodes relative to the primary tumor. Various definitions have been proposed for extent of lymphadenectomy. The Japanese Gastric Cancer Association (JGCA) definitions of D1, D1+, and D2 lymphadenectomy are listed in Table 87.4.

More extensive lymphadenectomy certainly provides better staging in gastric cancer, but the relationship between lymph node dissection and clinical outcomes is complex.[43] Historically, more extensive lymphadenectomy has been standard in Asian centers, with less extensive lymph node dissections performed in Western practice. A Cochrane meta-analysis of European and Asian RCTs found an improvement in disease-specific survival with D2 compared with D1 lymphadenectomy, but with higher perioperative mortality.[44] Much of the morbidity and mortality is thought to be related to the practice of distal pancreatectomy and splenectomy as part of the D2 lymphadenectomy in these trials. Modification of the D2 lymphadenectomy to a D1+ dissection excluding distal pancreatectomy and splenectomy resulted in decreased postoperative morbidity with equivalent disease-free survival in an Italian RCT. The Cochrane review also found that in Asian RCTs there was no survival benefit to D3 over D2 lymphadenectomy. Based on these data, NCCN guidelines recommend modified D2 lymph node dissection without routine pancreatectomy or splenectomy in centers experienced with this technique. For nonreferral centers, lymphadenectomy for gastric adenocarcinoma should incorporate at least a D1 lymphadenectomy. A D2 lymphadenectomy should only be performed if it can be done with low morbidity and almost no mortality. Western RCTs on extent of lymphadenectomy in gastric cancer are listed in Table 87.5.

In addition to the anatomic extent of lymph node dissection, the number of lymph nodes removed correlates with outcomes. Retrospective data show a trend toward improved survival with greater numbers of lymph nodes. It is not clear whether this is attributable directly to improved disease control from greater lymphadenectomy, from confounding because of stage migration (as patients who would otherwise be understaged are now classified as having node-positive disease status, improving the prognosis of both groups), or because it serves as a surrogate for overall surgical quality. Nevertheless, adequate lymphadenectomy is an indispensable staging tool. NCCN guidelines recommend pathologic analysis of a minimum of 16 nodes and suggest that over 30 lymph nodes is desirable. Minimally invasive approaches are associated with equivalent or higher rates of adequate lymphadenectomy.[45]

Minimally invasive surgery. Numerous retrospective propensity-matched studies and prospective RCTs have now established noninferior perioperative safety profiles and long-term survival outcomes with laparoscopic gastrectomy as compared with open gastrectomy in both Asian and Western cohorts and in both early and locally advanced disease.[46] Initial trials, including Japanese and Korean RCTs, did not identify differences in oncologic outcomes based on surgical approach for early-stage gastric cancer. Subsequent East Asian trials in locally advanced gastric cancer also showed noninferiority of the laparoscopic approach. Less prospective Western data have been reported, but data from European and North American series showed no differences in oncologic outcomes.[47–50] Much of the data for robotic-assisted gastrectomy is retrospective or too immature to assess long-term oncologic outcomes, but reported outcomes are generally equivalent between robotic-assisted and laparoscopic gastrectomy.[51] Two recent phase III prospective RCTs found that patients undergoing robotic-assisted gastrectomy had fewer postoperative complications and faster postoperative recovery than those undergoing

laparoscopic gastrectomy.[52,53] The prospective trials for minimally invasive gastrectomy generally excluded patients with T4b or N2 bulky disease; based on the characteristics of the disease and surgeon experience, open gastrectomy may be offered to these patients. It should be noted that prospective trials of minimally invasive techniques were performed in high-volume specialty centers. Laparoscopic and robotic gastrectomy and lymphadenectomy have a significant learning curve, and it can be difficult to achieve proficiency without high surgical volumes. Regardless of approach, the most important principle of surgery for gastric cancer is to perform an oncologically sound operation.

Postoperative management. Similar to other GI surgeries, Enhanced Recovery After Surgery (ERAS) protocols have been developed for perioperative care after gastrectomy. Specific recommendations from the ERAS society include no routine use of nasogastric (NG)/nasojejunal decompression, avoiding perianastomotic drains, and using minimally invasive approaches when possible.[54] A weak recommendation was also made for offering oral diet to patients undergoing a total gastrectomy starting on postoperative day 1. Randomized trials have generally shown small advantages with ERAS protocols in postoperative length of stay and pulmonary infections. However, there is a great deal of heterogeneity between trials in terms of patient populations, surgical techniques, and details of ERAS/fast-track protocols. For example, one trial found that ERAS benefited patients aged 45 to 74 years but resulted in worse outcomes for patients over 75 years old—specifically a higher readmission rate.[55] Moreover, much of the literature supporting ERAS protocols is retrospective, comparing the pre-ERAS era with current ERAS practice. A recent RCT in patients undergoing laparoscopic distal gastrectomy showed an advantage in clinical recovery of 15 hours, but this did not translate to any difference in actual hospital stay.[56] ERAS and other fast-track protocols after gastrectomy are an area of active research interest, and further optimization should elucidate ideal patient selection and balancing decreased length of stay with readmission rates.

Perioperative Therapy

Although surgical resection remains the cornerstone of curative-intent treatment for stomach cancer, perioperative multimodal treatment with chemotherapy and/or radiation has shown benefit, particularly for patients with stage II or higher disease, who are at significant risk of recurrence and mortality.[57] Recurrences are most commonly distant or peritoneal, but many patients also have locoregional recurrence, with a subset of 10% to 20% having only a local recurrence. Local recurrence rates are lower after D2 lymphadenectomy compared with D1 lymphadenectomy. For patients who recur, the prognosis is dismal, and there has been much focus on how to prevent recurrent disease with neoadjuvant and/or adjuvant therapies. A variety of approaches have been tested, and practices of multimodal therapy vary between countries and centers.

Chemotherapy. In Western countries, both pre- and postoperative chemotherapy is favored. The MAGIC and FLOT4-AIO studies were landmark RCTs establishing this paradigm. The MAGIC trial randomized patients with resectable gastric, GE junction, or distal esophageal cancer to surgery alone or perioperative chemotherapy with epirubicin, cisplatin and 5-fluorouracil (5-FU) (three cycles before and three cycles after resection), resulting in an improvement in OS for the perioperative chemotherapy group.[58] More recently, the FLOT4-AIL trial compared the MAGIC trial regimen with four cycles of preoperative and four cycles of postoperative 5-FU, leucovorin, oxaliplatin, and docetaxel (FLOT), resulting in improved OS in the FLOT arm.[59] Based on these data, NCCN guidelines recommend the FLOT regimen for patients with good performance status. Of note, completion of all postoperative chemotherapy cycles was relatively low in both the MAGIC and FLOT4 trials (41% and 46%, respectively). As such, the less toxic FOLFOX (5-FU, leucovorin, and oxaliplatin) regimen is recommended for patients with moderate to good performance status who may not tolerate FLOT.

In Eastern countries, the practice for resectable gastric cancer tends toward up-front resection followed by adjuvant chemotherapy if deemed necessary. The ACTS-GC trial randomized patients to surgery alone or surgery followed by adjuvant S-1 (an oral fluoropyrimidine) for 1 year, resulting in an improvement in OS in the S-1 arm.[60] The CLASSIC trial compared surgery alone with surgery followed by eight 3-week cycles of capecitabine plus oxaliplatin, resulting in improved disease-free and OS in the adjuvant chemotherapy group.[61] These trials also had relatively low rates of chemotherapy completion (66% and 67%, respectively), though better than the Western trials encompassing pre- and postoperative chemotherapy.

Chemoradiotherapy. The US INT-0116 trial was an early milestone study that compared gastrectomy alone or combined with adjuvant 5-FU and radiotherapy, demonstrating improved overall and recurrence-free survival in the chemoradiotherapy group.[62] A major criticism of this trial is that the majority of patients did not receive even a D1 lymphadenectomy, and consequently, the survival advantage with chemoradiation appeared to be mainly through reduction of locoregional recurrence. As multiagent chemotherapy regimens were developed, additional RCTs compared chemotherapy alone with chemoradiotherapy. The ARTIST trial randomized South Korean patients after gastrectomy to adjuvant capecitabine and cisplatin with or without radiation therapy.[63] There was no overall or disease-free survival advantage in the cohort as a whole, although on subgroup analysis, node-positive patients appeared to have a disease-free survival benefit. Subsequently, the ARTIST 2 trial randomized only node-positive patients to adjuvant (1) S-1, (2) S-1 and oxaliplatin, or (3) S-1 and oxaliplatin with radiation therapy.[64] Disease-free survival was longer in the S-1 and oxaliplatin group compared with S-1 alone, but the addition of radiation therapy did not confer any further benefit. Based on these trials, which specified D2 lymph node dissection, NCCN guidelines recommend postoperative chemotherapy only after up-front gastrectomy with adequate lymphadenectomy; however, the addition of radiation therapy is recommended for patients who underwent less than a D2 lymphadenectomy.

The CRITICS trial randomized patients who received preoperative epirubicin, cisplatin or oxaliplatin, and capecitabine to either postoperative chemotherapy with the same drugs or chemoradiation with capecitabine and cisplatin.[65] In this context, there was no overall or disease-free survival benefit to the addition of radiation therapy. The CROSS trial included patients with esophageal or GE junction cancers (GEJCs, including 23% squamous cell cancers) and randomized to neoadjuvant chemoradiation (with carboplatin and paclitaxel) versus surgery alone.[66] There was an improvement in OS with chemoradiation, but this was most pronounced in patients with squamous histology. Nevertheless, based on this trial, NCCN guidelines include preoperative chemoradiation as an option for patients with gastric cancer.

Immunotherapy. The advent of checkpoint immunotherapy is an exciting recent development in oncology, but at this point only a minority of patients with gastric cancer have been shown to benefit significantly from this approach. In metastatic gastric cancer, MSI-high and mismatch repair-deficient (dMMR) tumors and those with high expression of PD-L1 are clinically approved indications for checkpoint inhibition. Additionally, as discussed earlier, EBV-associated tumors tend to respond well to immunotherapy.

Importantly, MSI-high tumors do not respond to conventional cytotoxic chemotherapy.[67] Currently, the standard approach for locally advanced, nonmetastatic MSI-H gastric cancer is up-front surgical resection without neoadjuvant or adjuvant therapy. MSI-H gastric cancers have a high response rate to checkpoint blockade, making perioperative immunotherapy a potentially attractive option. There is a lack of head-to-head data on choice of immunotherapy drugs or timing in relation to surgery. There are now two phase II trials (NEONIPIGA and INFINITY) showing an approximately 60% pathologic complete response rate in MSI-high/dMMR gastric cancer with neoadjuvant dual checkpoint inhibition (targeting both programmed cell death 1 [PD-1] and cytotoxic T-lymphocyte–associated protein 4 [CTLA-4]). Long-term data are lacking, but the possibility of nonoperative management with endoscopic and imaging surveillance may be feasible in a subset of MSI-high/dMMR gastric cancers that show clinical complete responses to immunotherapy.

Targeted therapy. In addition to MSI/MMR, PD-L1, and EBV status, pathologic analysis of gastric cancer should include HER2 analysis, as tumors that overexpress or have amplified HER2 are eligible for anti-HER2 therapy. Trastuzumab is a monoclonal anti-HER2 antibody that should be added to first-line chemotherapy for HER2-overexpressing gastric cancer. Based on the anti-HER2 antibody platform, trastuzumab deruxtecan (an antibody-drug conjugate that delivers targeted chemotherapy to HER2-positive cells) was recently FDA approved in the second-line setting for patients with unresectable or metastatic HER2-amplified gastric cancer.

In terms of HER2-positive blockade for locally advanced gastric cancer, the PETRARCA trial studied the effect of perioperative trastuzumab, pertuzumab, and FLOT compared with FLOT alone in patients with cT2-T4 and/or N+ gastric or GEJC and HER2-positive overexpression.[68] The pathologic complete response rate was significantly improved in the trastuzumab/pertuzumab group compared with that in the group receiving FLOT alone (35% vs. 12%, $p = 0.02$), as was the rate of pathologic lymph node negativity (65% vs. 39%). However, the trastuzumab/pertuzumab group experienced more grade 3 or greater adverse events, particularly diarrhea and leukopenia. Ultimately, the negative results of the JACOB trial, which evaluated the efficacy of dual-HER2 therapy and chemotherapy in metastatic GC/GEJC, led to a premature termination of the PETRARCA trial.[69]

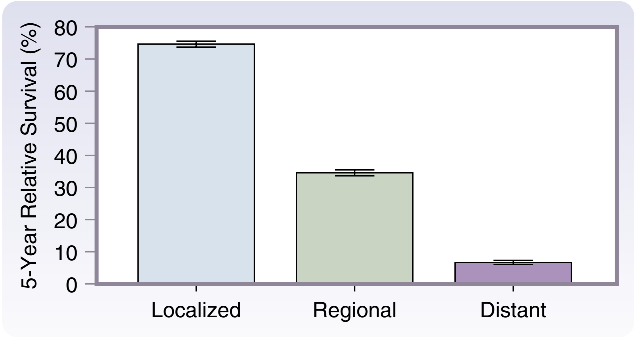
The phase II INNOVATION trial is currently underway for patients with resectable GC/GEJC.[70] This trial is investigating whether neoadjuvant and adjuvant trastuzumab or trastuzumab and pertuzumab in combination with chemotherapy is more efficacious than chemotherapy alone. The chemotherapy backbone of this trial was modified from cisplatin + capecitabine to FLOT based on the FLOT4-AIO trial. Preliminary results show a trend toward increased major pathologic response with the addition of trastuzumab (37% vs. 23% with chemotherapy alone), which was more pronounced after protocol modification (53% vs. 33%), but no improvement with the addition of both trastuzumab and pertuzumab. Study completion with follow-up survival data is expected in 2028.

Outcomes

The overall incidence and mortality rate of gastric cancer in the United States have been declining since 1930, likely because of changes in diet such as decreased sodium intake, changes in food storage and preparation, decreased smoking, and improved treatment options. Nonetheless, the overall 5-year survival remains poor, at approximately 35%. More than 60% of patients present with locally advanced or distant disease. For patients who undergo a potentially curative resection, overall 5-year survival rates range from 25% to 75%; however, for the subset with early gastric cancer, cure rates are greater than 80%. For patients who present with distant disease, 5-year survival is only 5% to 10% (Fig. 87.8).

Recurrence and Surveillance

Recurrence rates after gastrectomy are high, from 30% to 90%, depending on the series. Most recurrences occur within the first



Stomach
SEER 5-Year Relative Survival Rates, 2013-2019
By Stage at Diagnosis, Both Sexes, All Races / Ethnicities, All Ages

Data source:
- SEER Incidence data, November 2022 submission (1975-2020) SEER 22 registries [https//seer.cancer.gov/registries/terms.html] (excluding Illinois and Massachusetts).
- Expected survival life tables [https//seer.cancer.gov/expsurvival/] by socioeconomic standards.

Methodology:
- The 5-year survival rates are calculated using monthly intervals.

Race/Ethnicity/Coding:
- For more details on SEER race/ethnicity groupings and changes made to the grouping for this year's data release, please see race and hispanic ethnicity changes [https://seer cancer gov/seerstat/variables/see/race-ethnicity/).
- Incidence data for Hispanics and non-Hispanics are based on the NAACCR Hispanic Latino Identification Algorithm (NHIA).
- Rates for American Indians/Alaska Natives only include cases that are in a purchased/referred care delivery area (PRCDA).

Cancer site coding:
- See SEER explore cancer site definitions (https://seer.cancer.gov/statistics-network/explore/cancer-sites.htm) for details about the cancer site coding used for SEER incidence data.

Created by https://seer.cancer.gov/statistics-network/explorer on Wed Oct 04 2023.

FIGURE 87.8 The 5-year relative survival rates in patients with stomach cancers by stage at diagnosis. *SEER,* The Surveillance, Epidemiology, and End Results Program. (From SEER database, seer.cancer.gov.)

2 years.[71] Locoregional recurrence is seen in about 40% of these patients. As stated earlier, the rate of locoregional recurrence depends on the extent of lymphadenectomy, with lower rates after D2 lymphadenectomy compared with D1. The most common sites of locoregional recurrence are the gastric remnant at the anastomosis, in the gastric bed, and in the regional nodal basins. The predominant sites of systemic recurrence are the liver and peritoneum.

Although all patients should be followed systematically, the evidence for how this should occur is unclear, and there is currently no evidence that more intensive follow-up improves long-term survival. The NCCN recommends a complete history and physical examination every 3 to 6 months for 1 to 2 years, then every 6 to 12 months for 3 to 5 years. Laboratory tests, including complete blood count and chemistry profile, should be performed as clinically indicated. Given the nutritional sequelae of gastrectomy, iron studies and levels of vitamin B_{12} and vitamin D can also be obtained. Postgastrectomy patients are at risk of calcium loss, so bone density tests should be performed for those at risk of osteopenia and osteoporosis. For patients with pathologic stage II or higher disease, CT chest/abdomen/pelvis should be obtained every 6 months for the first 2 years, then annually up to 5 years, and for all patients as indicated if there is clinical suspicion of recurrence. Sensitivity for detecting peritoneal recurrence is low. Patients remain at risk for second primary gastric cancers after partial gastrectomy and should undergo surveillance with upper endoscopy; typically, the first surveillance EGD will be 1 year after resection, then every other year thereafter, or as indicated clinically. For patients who were successfully treated with endoscopic resection, endoscopy should be performed every 6 months for 1 year, then annually for 3 years.

GASTROINTESTINAL STROMAL TUMOR

Epidemiology and Mutational Patterns

GI stromal tumors (GISTs) are the most common mesenchymal neoplasm of the GI tract. Gastric GISTs can manifest at any age, although they typically manifest in patients older than 50 years. Approximately 5% of GISTs are associated with an underlying heritable mutation such as familial GIST syndrome (mutation in KIT or PDGFRA), neurofibromatosis type 1, or Carney-Stratakis syndrome (GIST and paraganglioma with or without pulmonary chondroma). Originally thought to be a type of smooth muscle sarcoma, they are now known to be a distinct tumor derived from the interstitial cells of Cajal, GI pacemaker cells that reside in the muscularis propria layer. The incidence was difficult to assess previously given variable histologic definitions. However, since the discovery of KIT (CD117), DOG1, and CD34 expression in GIST, more accurate estimates range from 7 to 15 cases per million per year. KIT is a receptor tyrosine kinase, and approximately 95% of GISTs express KIT. KIT mutations are identified in 75% to 85% of GISTs. Most GISTs that lack a KIT mutation will have a mutation in platelet-derived growth factor receptor alpha (PDGFRA). Of the small KIT- and PDGFRA-wild-type subset, many are succinate dehydrogenase (SDH) deficient. Although GISTs can appear anywhere within the GI tract, they most commonly arise in the stomach (40%–60%), small intestine (20%– 40%), and colon/rectum (5%–15%). GISTs vary considerably in their presentation and clinical course, ranging from small, very slow-growing tumors to massive lesions with necrosis, hemorrhage, and wide metastases. Their pathology, presentation, and management as they relate to the stomach are discussed here.

Diagnosis and Workup

Most GISTs manifest with nonspecific symptoms, typically with early satiety, bloating, or vague abdominal pain. Bleeding can occur and is generally in the form of melena or, less frequently, frank hematemesis. Tumor rupture with intraabdominal hemorrhage is uncommon, but when it occurs, it may require emergent surgical intervention. Many patients remain asymptomatic, and their tumors are discovered incidentally with cross-sectional imaging performed for other indications.

Patients are evaluated with upper endoscopy, on which a smooth-appearing, round, submucosal tumor can be identified, occasionally containing an area of central ulceration. Upper endoscopy may be normal when tumors are exophytic. Because of the submucosal nature of the tumor, obtaining tissue for histologic and immunohistochemical analysis via conventional endoscopic forceps biopsy results in a low diagnostic yield. EUS-directed FNA or fine-needle biopsy (FNB) results in superior diagnostic accuracy, with a sensitivity of >80% and specificity of 100% in diagnosing GIST. Given the expense and specialized expertise involved in performing EUS-directed FNA, in addition to the fact that most submucosal GI tumors require surgical resection regardless of histology, some experts have argued that routine preoperative pathologic diagnosis is not needed for such tumors. Presently, preoperative biopsy is not recommended if there is a high suspicion for GIST and the patient is otherwise operable, but it is preferred if there is metastatic disease or if the patient is being considered for neoadjuvant therapy. CT of the abdomen and pelvis with IV contrast is used to assess for metastatic disease. MRI is preferred in patients who cannot receive IV contrast or for rectal GISTs. Pathologically, GISTs can either have a spindle cell or epithelioid appearance. Immunohistochemical staining for CD117, DOG1, CD34, and/or PDGFRA is used to confirm the diagnosis.

Treatment

Surgery

The mainstay of treatment is complete surgical resection. Tumors that are symptomatic or greater than 2 to 3 cm in diameter should be resected, but the treatment for smaller tumors is controversial. Tumors that are less than 2 to 3 cm but that have high-risk features on endoscopy and EUS, such as irregular borders, ulceration, echogenic foci, and heterogeneity, should be resected, whereas tumors without such features can be observed with repeat endoscopy and EUS at 6- to 12-month intervals. Depending on tumor size and location, resection can include wedge resection, sleeve gastrectomy, segmental, or, rarely, total gastrectomy, with or without en bloc resection of adjacent organs. GISTs generally have noninfiltrative margins; thus, a 1-cm gross margin of normal tissue almost always results in a negative margin. GISTs rarely metastasize to lymph nodes, so lymphadenectomy is not needed. These tumors are often friable and prone to rupture, so tumors should be handled carefully intraoperatively to avoid rupture and spillage of tumor cells.

As with gastric adenocarcinoma, minimally invasive approaches are acceptable for resection of GISTs provided that oncologic principles are not compromised. For gastric GISTs, size and location are the main factors affecting surgical approach. In particular, smaller tumors that are distant from the GE junction and from the pylorus are most amenable to laparoscopic or robotic resection. NCCN guidelines state that a minimally invasive approach may be considered for select GISTs in favorable anatomic locations by surgeons with appropriate minimally invasive experience.

Adjuvant and Neoadjuvant Therapy

GISTs can metastasize to the liver and to the peritoneal cavity. Locoregional recurrence after surgical resection is rare. Gastric GISTs carry a more favorable prognosis compared with GISTs in other locations in terms of recurrence. The two primary prognostic factors for gastric GISTs are tumor size and mitotic rate. Based on a long-term follow-up study of 1700 patients with gastric GISTs, metastatic potential based on the combination of these two factors has been established.[72] These factors also predict the likelihood of recurrence after surgery for gastric GISTs.[73]

Adjuvant therapy for GIST changed dramatically with the discovery of the tyrosine kinase inhibitor (TKI) imatinib (Gleevec). Originally designed to treat chronic myelogenous leukemia, it has proven in RCTs to be an effective treatment modality for patients with GIST. The ACOSOG Z9001 phase III, placebo-controlled, randomized trial of 713 patients with c-kit+ tumors 3 cm or larger who underwent complete resection found that patients treated with imatinib for 1 year had a significantly improved 1-year recurrence-free survival (98% vs. 83%, $P < 0.0001$).[74] This difference was even more pronounced for patients with larger tumors. The Scandinavian Sarcoma Group XVIII trial compared an extended 36-month course of adjuvant imatinib with a 12-month course after resection for 400 patients with high-risk GISTs (defined as >10 cm tumor, mitotic count >10/50 high-power field [HPF], both tumor >5 cm and mitotic count >5 per 50 HPF, or tumor rupture). In the second planned analysis of the trial, patients in the extended treatment arm had higher 5-year recurrence-free survival (71.1% vs. 52.3%, $P < 0.001$) and OS (91.9% vs. 85.3%, $P = 0.036$).[75] The results of these trials have established a 3-year course as the standard of care after surgical resection of high-risk GIST, though longer duration of therapy is being explored, as it appears the protective effect of imatinib does not persist after drug discontinuation. Imatinib appears to prevent microscopic residual disease from growing but does not eradicate it. Thus, some oncologists recommend lifelong therapy for those at moderate to high risk of harboring microscopic disease.

Imatinib has also been reported to be successful in the neoadjuvant treatment of patients with nonmetastatic but unresectable disease, in some cases resulting in conversion to resectability. Currently, patients with locally advanced, borderline resectable disease or in whom tumor shrinkage would increase the likelihood of organ preservation should also be considered for neoadjuvant therapy. As stated previously, patients with limited metastatic disease can be offered neoadjuvant imatinib followed by possible metastasectomy based on clinical response.

Patients presenting with recurrent or metastatic disease are primarily treated with imatinib or a second-line TKI (see later), but a subset of patients may benefit from surgical intervention. Two trials addressing this question were begun in Europe and in China, but both failed to recruit quickly enough to meet target accrual. In the absence of randomized trials, single-institution and multi-institutional retrospective studies document long-term disease control and longer OS for selected patients with limited metastatic disease who undergo metastasectomy. In general, resection appears to benefit responding patients (i.e., those who have a partial response, stable disease, or focal progression and possibly those with isolated sites of progression) but has little to offer those who experience generalized or multifocal disease progression while receiving a TKI. A series of 323 patients found that response to neoadjuvant imatinib predicted clinical response after metastasectomy.[76] Among the patients receiving imatinib, radiographic response at the time of surgery was predictive of both progression-free survival (PFS) and OS after surgery:

- Responsive disease—Median PFS 36 months, median OS not reached
- Stable disease—Median PFS 30 months, median OS 110 months
- Unifocal progressive disease—11 months, median OS 59 months
- Multifocal progressive disease—6 months, median OS 24 months

Patients with responsive or stable disease had a median PFS of 30 to 36 months, whereas those with unifocal or multifocal progressive disease had median PFS of only 6 to 11 months. Some surgeons propose that patients be treated for 6 to 9 months with neoadjuvant systemic therapy and subsequently evaluated for surgery if the disease appears completely grossly resectable. Although it has been shown that tumor load continues to decrease even after 1 year of imatinib, the median time to best response is 3.5 months, and there is little incremental tumor shrinkage after 9 months. The timing of surgery in this setting is typically 6 to 9 months after initiation of neoadjuvant therapy. Restaging imaging is useful to plan for surgery at the time of maximal response. Patients with isolated liver metastases can be considered for liver metastasectomy, radiofrequency ablation, hepatic artery embolization, chemoembolization, or radioembolization using yttrium-90–tagged microspheres, radiofrequency ablation, or hepatic arterial embolization, which have shown some benefit in nonrandomized series.

Fig. 87.9 is an algorithm for using imatinib in the treatment of GISTs in the neoadjuvant, adjuvant, and palliative settings. Patients who progress on imatinib or are intolerant to the drug are typically offered second-line TKIs such as sunitinib or regorafenib, although the duration of PFS is shorter on subsequent-line TKIs compared with first-line imatinib.

Relative differences in sensitivity to TKIs based on KIT and PDGFRA mutational status have been recognized for over 20 years based on in vitro data and subgroup analyses of imatinib trials (Fig. 87.10). KIT exon 11 mutations are most common and are most sensitive to imatinib therapy, whereas KIT exon 9 mutations are rarer and more imatinib resistant; however, increased imatinib doses can improve response in KIT exon 9 mutant GISTs. Other KIT mutations, including those in exon 13 and 17, occur most commonly as secondary events in the setting of imatinib resistance. PDGFRA mutations tend to have poor responses to imatinib, particularly the D842V mutation. First-line TKI therapy in patients with PGDFRA D842V mutations should be avapritinib based on a phase I trial that achieved a 91% radiographic response rate in this population.[77] An algorithm for TKI treatment in advanced GIST is depicted in Fig. 87.10.

GASTRIC LYMPHOMA

Epidemiology

The stomach is the most common site of extranodal lymphoma. However, primary gastric lymphoma is still relatively uncommon, accounting for approximately 3% of gastric cancers. Patients often present with vague symptoms, such as epigastric pain, early satiety, and fatigue. Constitutional B symptoms (i.e., fevers, night

sweats) occur in only about 10% of patients. Lymphomas occur in older patients, with the peak incidence in the sixth and seventh decades, and there is a slight male predominance. Gastric lymphomas usually occur in the gastric antrum but can arise from any part of the stomach. Patients are considered to have primary gastric lymphoma if the stomach is the exclusive or predominant site of disease. Several conditions have been shown to be associated with gastric lymphoma, including *H. pylori* infection, certain autoimmune diseases (i.e., rheumatoid arthritis, systemic lupus erythematous), immunosuppression, and celiac disease.

Pathology

In the management of gastric lymphomas, as in the management of nodal lymphomas, it is important to determine not only the stage of disease but also the subtype of lymphoma. There are many classification systems for lymphomas (Table 87.6). The most common gastric lymphoma is diffuse large B-cell lymphoma (DLBCL; 45%–60%), followed by gastric mucosa-associated lymphoid tissue (MALT) lymphoma (40%–50%). Less commonly, peripheral T-cell lymphoma (1%–4%) and mantle cell and follicular lymphomas (both <1%) are seen.

DLBCLs are generally primary lesions; however, they may also occur from progression of less aggressive lymphomas, such as chronic lymphocytic leukemia, small lymphocytic lymphoma, follicular lymphoma, and MALT lymphoma. Immunodeficiency and *H. pylori* infection are risk factors for the development of primary DLBCL.

Evaluation and Staging

Endoscopy with biopsy is indicated for workup of patients with suspected gastric lymphoma. Occasionally, a submucosal growth pattern renders endoscopic biopsies nondiagnostic. EUS is useful to determine the depth of gastric wall invasion and to evaluate for regional lymph node involvement. Evidence of distant disease should be sought through upper airway examination to evaluate the Waldeyer tonsillar ring, bone marrow biopsy, and PET/CT to detect lymphadenopathy. Biopsies should be performed of enlarged lymph nodes. Histologic *H. pylori* testing should be performed and, if negative, confirmed by serology. Staging is important both for prognosis and treatment decision-making. The modified Lugano staging system is the most widely used for gastric lymphoma (Table 87.7).

Treatment

Surgeons should be aware that gastric lymphoma rarely requires surgical resection either for diagnosis or treatment.

Diffuse Large B-Cell Lymphoma Oncologists use multiagent chemotherapy regimens for patients with gastric lymphoma. The most common chemotherapeutic combination is R-CHOP (rituximab, cyclophosphamide, hydroxydaunomycin [doxorubicin], Oncovin [vincristine], prednisone). A prospective randomized study evaluated several treatment strategies—surgical resection, resection plus radiation, resection plus chemotherapy, chemotherapy alone—in patients with early stage (stage IE or II1) disease.[78] The addition of chemotherapy was essential, with the surgery plus chemotherapy and chemotherapy-alone groups having significantly higher OS than the surgery-alone and surgery plus radiation groups. However, the addition of surgery to chemotherapy did not improve outcomes and increased morbidity. Thus, the primary role of surgery is currently limited to patients with symptomatic recurrence after treatment failure and patients who develop complications, such as bleeding, gastric outlet obstruction, or perforation. Chemotherapy for gastric lymphoma is associated with a 5% rate of gastric perforation and GI bleeding.

Mucosa-Associated Lymphoid Tissue Lymphoma

Gastric MALT lymphoma is lower grade than DLBCL and is usually preceded by *H. pylori*–induced gastritis. Evidence of *H. pylori* infection can be found in almost every case of gastric

TABLE 87.7 Lugano Staging System for Gastrointestinal Lymphoma

STAGE	DESCRIPTION
I	Tumor confined to gastrointestinal tract
IE1	Involvement of mucosa ± submucosa
IE2	Involvement of muscularis propria ± serosa
II	Tumor extension into abdomen
II_1	Involvement of local nodes (paragastric for gastric lymphoma)
II_2	Involvement of distal nodes (paraaortic, paracaval, pelvic, or inguinal)
IIE	Serosa penetration to involve adjacent organs/tissues
IV	Disseminated extranodal involvement or supradiaphragmatic nodal involvement

MALT lymphoma. Genetically, MALT lymphoma is characterized by four chromosomic translocations: t(1;14), t(3;14), t(11;18), and t(14;18). The t(1;14), t(11;18), and t(14;18) translocations result in increased nuclear factor-κB activity, with resultant enhanced cell survival. The t(3;14) translocation increases FOXP1 transcription factor levels, which has been shown to expand marginal zone B cells.

Given the strong association with *H. pylori* and the low-grade MALT lymphoma, patients should be evaluated for active infection. Patients with early stage MALT lymphomas and active *H. pylori* infection may be effectively treated by *H. pylori* eradication alone. Successful eradication results in remission in more than 75% of cases. However, careful follow-up is necessary, with repeat endoscopy in 2 months to document clearance of the infection and biannual endoscopy for 3 years to document regression. Some patients continue to demonstrate the lymphoma clone after *H. pylori* eradication, suggesting that the lymphoma became dormant rather than disappearing. The presence of transmural tumor extension, nodal involvement, transformation into a large cell phenotype, and nuclear BCL-10 expression all predict failure after *H. pylori* eradication alone. Additionally, some patients with MALT lymphoma are *H. pylori*–negative. In these patients, consideration should be given to radiation therapy (if all the involved sites can be encompassed in a single field) and chemotherapy. A recent MALT lymphoma prognostic index was developed that identified three primary risk factors: age of 70 or above, stage IV disease, and elevated lactate dehydrogenase (LDH) level. The 5-year OS rates were 98.7% for no risk factors, 93.1% for one risk factor, and 64.3% for two to three risk factors ($P < 0.0001$).[79]

GASTRIC NEUROENDOCRINE TUMORS

Gastric neuroendocrine tumors (NETs), also referred to as *carcinoid tumors,* are a rare malignancy that arise from neuroendocrine precursor cells and can manifest at any site in the body. The most common sites in the GI tract are the small intestine, rectum, and appendix. The stomach is becoming an increasing common site of NETs, now representing 8% of tumors. This increasing incidence is thought to be due to a combination of improved surveillance and the widespread use of PPIs. Unlike other GI tract NETs, gastric NETs are typically nonfunctioning and rarely cause carcinoid syndrome.

There are three distinct subtypes of gastric NETs (Table 87.8). Type I gastric NETs are the most common, accounting for 70% to 80% of cases. They are associated with chronic achlorhydria from atrophic gastritis or autoimmune gastritis, leading to chronically elevated gastrin levels. Type I gastric NETs are typically seen as multiple small tumors confined to the mucosa and submucosa with a relatively benign course and favorable prognosis. The tumors are derived from enterochromaffin-like (ECL) cells. It is thought that ECL cells develop into NETs after chronic stimulation by high gastrin levels. This is supported by the observation that regression of gastric NETs can be achieved by antrectomy, which is occasionally recommended. Patients with type I gastric NETs are usually diagnosed in their 60s or 70s during endoscopic evaluation. They are more common in females. Endoscopically, the tumors are usually smaller than 1 cm, are often multiple, and may appear as polypoid lesions with a small central ulceration. These tumors are usually indolent and generally represent a benign condition. Type II gastric NETs are associated with hypergastrinemia in the setting of gastrinomas (Zollinger-Ellison syndrome), typically of the pancreas or duodenum, and often in the setting of multiple endocrine neoplasia type 1 (MEN1). They account for 5% to 10% of gastric NETs. These tumors are also thought to arise from ECL cells stimulated by elevated serum gastrin levels. Type III gastric NETs are known as *sporadic NETs* because they are independent of gastrin level. They account for 20% of gastric NETs and are the most aggressive. Nodal or hepatic metastases are present in up to 65% of patients who come to resection.

Diagnosis of gastric NET is established on EGD with biopsy of the lesion. EUS can be performed subsequently to assess for depth of invasion. Based on North American Neuroendocrine Tumor Society recommendations,[80] gastric pH and serum gastrin levels should be obtained; for type I, antiintrinsic factor and anti–parietal cell antibodies help confirm the diagnosis. Chromogranin A levels may be elevated and serve as a biomarker for type III tumors, but false positives can result from PPI use and renal insufficiency. CT or MRI should be used to evaluate for metastatic disease for type II and type III tumors. Somatostatin-receptor imaging (most commonly ^{68}Ga-DOTATATE PET/CT) can be useful in some instances, such as evaluation of metastatic disease, but need not be obtained routinely.

Management of type I gastric NETs is usually endoscopic resection and surveillance, and surgery is reserved only for tumors that cannot be managed endoscopically. For type II lesions <1 cm, surveillance or endoscopic removal is indicated. For those >1 cm in size, endoscopic removal with subsequent endoscopic surveillance is recommended. For large polyps (>2 cm in size), complete removal may not be possible endoscopically; in that case, or in cases of six or more large polyps, wedge resection or partial gastrectomy may be required. In patients with type II NETs, gastrinoma resection should be performed as well, if possible. Patients with localized type III NETs should undergo oncologic resection with lymphadenectomy. For patients with recurrent or metastatic disease, somatostatin analogues or chemotherapy can be used to decrease the burden of disease and treat carcinoid syndrome. Liver-directed therapies, including

TABLE 87.8 Gastric Carcinoid Types

	TYPE I	TYPE II	TYPE III
Percentage of gastric NETs	70%–80%	5%–10%	10%–15%
Associated pathology	Pernicious anemia, prolonged PPI use	ZES, MEN1	n/a
Location	Fundus or body	Fundus, body, antrum	Fundus or antrum
Tumor number	Multiple	Multiple	Single
Gastric acid level	Low	High	Normal
Serum gastrin level	High	High	Normal
Prognosis	Excellent	Good	Poor

MEN1, Multiple endocrine neoplasia type 1; *NETs,* neuroendocrine tumors; *PPI,* proton pump inhibitor; *ZES,* Zollinger-Ellison syndrome.

ablation and embolization, may be useful in cases of liver-dominant metastasis. Peptide receptor radionuclide therapy (PRRT), which is a form of systemic radiotherapy using radionuclides coupled with a somatostatin analog, is a newer modality available for treatment of NETs expressing the somatostatin receptor and is useful in cases of metastatic disease and carcinoid syndrome.

HETEROTOPIC PANCREAS

Heterotopic pancreas (i.e., functioning pancreatic tissue is found in an abnormal anatomic location) is found in 0.5% to 14% of autopsy specimens. The most common location is within the stomach, typically along the antral greater curvature. Symptomatic patients generally present with vague abdominal pain. There have been reports of pancreatitis, islet cell tumors, and pancreatic adenocarcinoma within these lesions. On endoscopy and CT, they are frequently small submucosal masses and may be confused with a GIST or some other gastric neoplasm. The treatment is surgical excision, and the diagnosis is confirmed pathologically.

HYPERTROPHIC GASTRITIS (MÉNÉTRIER DISEASE)

Ménétrier disease (hypoproteinemic hypertrophic gastropathy) is a rare disease (<1000 reported cases) characterized by massive gastric folds in the fundus and body of the stomach, giving the mucosa a cobblestone or cerebriform appearance. The antrum is typically spared. Histologic examination reveals foveolar hyperplasia (expansion of surface mucus cells), with decreased or absent parietal cells. The condition is also associated with protein loss from the stomach, excessive mucus production, and hypochlorhydria or achlorhydria. The cause of Ménétrier disease is unknown, but it has been associated with cytomegalovirus infection in children and *H. pylori* infection in adults. Also, increased levels of transforming growth factor-α have been noted in the gastric mucosa of patients with the disease, which can stimulate epithelial cell growth and inhibit gastric acid secretion. Patients often present with epigastric pain, vomiting, weight loss, decreased appetite, and peripheral edema. Typical gastric mucosal changes can be detected by radiographic or endoscopic examination. Biopsy should be performed to establish the diagnosis and to rule out gastric carcinoma or lymphoma. Medical treatment yields inconsistent results; however, some benefit has been shown with the use of acid suppression, octreotide, and cytomegalovirus or *H. pylori* eradication. Total gastrectomy should be performed in patients who continue to have massive protein loss despite optimal medical therapy and high-protein diet, continue to have intractable pain, or if dysplasia or carcinoma develops. One series estimated 73% OS at 5 years and 65% at 10 years after diagnosis, with a 9% risk of gastric cancer after 10 years of follow-up. Given the increased risk of gastric neoplasms in patients with Ménétrier disease, patients should undergo endoscopic surveillance every 1 to 2 years.

Cancer Genome Atlas Research Network. Comprehensive molecular characterization of gastric adenocarcinoma. *Nature*. 2014;513(7517):202-209.

Cristescu R, Lee J, Nebozhyn M, et al. Molecular analysis of gastric cancer identifies subtypes associated with distinct clinical outcomes. *Nat Med*. 2015;21(5):449-456.

These two major transcriptomic studies used molecular classifiers to identify subgroups of gastric adenocarcinoma with distinct clinical features and outcomes. The Cancer Genome Atlas classification system identified Epstein-Barr virus–positive (EBV), microsatellite instability (MSI), genomically stable (GS), and chromosomal instability (CIN) subtypes. In the current era of immunotherapy, MSI status (and, to a lesser extent, EBV status, because of its relative rarity) is now used as a predictor of response to checkpoint inhibition therapy.

Cunningham D, Allum WH, Stenning SP, et al. Perioperative chemotherapy versus surgery alone for resectable gastroesophageal cancer. *N Engl J Med*. 2006;355(1):11-20.

Al-Batran SE, Homann N, Pauligk C, et al. Perioperative chemotherapy with fluorouracil plus leucovorin, oxaliplatin, and docetaxel versus fluorouracil or capecitabine plus cisplatin and epirubicin for locally advanced, resectable gastric or gastro-oesophageal junction adenocarcinoma (FLOT4): a randomised, phase 2/3 trial. *Lancet*. 2019;393(10184):1948-1957.

These two large randomized controlled trials established the benefit of perioperative chemotherapy on overall survival in gastric adenocarcinoma. The earlier MAGIC trial used pre- and postoperative epirubicin, cisplatin, and 5-FU (ECF), resulting in improved overall survival compared with surgery alone. The subsequent FLOT4 trial showed that pre- and postoperative 5-FU, leucovorin, oxaliplatin, and docetaxel (FLOT) resulted in improved overall survival compared with the ECF regimen.

DeMatteo RP, Ballman KV, Antonescu CR, et al. Adjuvant imatinib mesylate after resection of localised, primary gastrointestinal stromal tumour: a randomised, double-blind, placebo-controlled trial. *Lancet*. 2009;373(9669):1097-1104.

Joensuu H, Eriksson M, Sundby Hall K, et al. Survival outcomes associated with 3 years vs 1 year of adjuvant imatinib for patients with high-risk gastrointestinal stromal tumors: an analysis of a randomized clinical trial after 10-year follow-up. *JAMA Oncol*. 2020;6(8):1241-1246.

These two major randomized controlled trials established the role of adjuvant imatinib after surgical resection for the treatment of localized GIST. The first study by DeMatteo and colleagues showed significantly less recurrence in patients who received imatinib compared with patients who did not; this was especially pronounced for patients at high risk of developing metastatic disease. The second trial by Joensuu and colleagues showed that a 36-month course of adjuvant imatinib was superior to a 12-month course in terms of disease-free and overall survival. These studies established long-term adjuvant treatment with imatinib as the standard of care for patients with GISTs. The optimal length of adjuvant treatment for intermediate- and high-risk GISTs remains controversial.

Miettinen M, Sobin LH, Lasota J. Gastrointestinal stromal tumors of the stomach: a clinicopathologic, immunohistochemical, and molecular genetic study of 1765 cases with long-term follow-up. *Am J Surg Pathol*. 2005;29(1):52-68.

Gold JS, Gönen M, Gutiérrez A, et al. Development and validation of a prognostic nomogram for recurrence-free survival after complete surgical resection of localised primary gastrointestinal stromal tumour: a retrospective analysis. *Lancet Oncol*. 2009;10(11):1045-1052.

These two retrospective studies in large cohorts identified prognostic factors associated with metastasis and recurrence of GISTs. Both studies identified tumor size and mitotic rate as negative prognostic factors. Currently, risk stratification and recommendation for or against adjuvant tyrosine kinase inhibitor therapy is based on these factors.

Mocellin S, McCulloch P, Kazi H, Gama-Rodrigues JJ, Yuan Y, Nitti D. Extent of lymph node dissection for adenocarcinoma of the stomach. *Cochrane Database Syst Rev*. 2015;2015(8):CD001964.

The appropriate extent of lymphadenectomy for gastric adenocarcinoma was a subject of debate for many years, with most Western centers favoring D1 lymphadenectomy and East Asian centers favoring more extensive D2 or even D3 lymphadenectomy. Randomized clinical trials in both Western and Eastern centers, as described in this Cochrane review, have now converged on D2 lymphadenectomy as providing appropriate N staging with an acceptable safety profile. In long-term follow-up, D2 lymphadenectomy is associated with improved cancer-specific survival compared with D1.

ANATOMY AND PHYSIOLOGY

Anatomic variations in biliary anatomy and of the vascular structures in the hepatoduodenal ligament are common, occurring in up to 30% of patients. The optimal management of patients with biliary tract diseases is highly dependent on a thorough understanding of both normal anatomy and the common variations.

The common bile duct (CBD) lies anterior to the hepatic arteries (proper hepatic artery and right hepatic artery) and portal vein in the duodenohepatic ligament (Fig. 88.1). At the level of the hilum the biliary bifurcation abuts the base of segment IVB of the liver and assumes a location superior to the intrahepatic branches of the portal vein and hepatic arteries. The left hepatic duct retains a longer transverse extrahepatic portion and travels under the edge of segment IVB from the umbilical fissure to the biliary bifurcation making it more surgically accessible. The left duct drains segments I, II, III, and IV, with the most distal branch draining segment IVA. Further superolateral, the ducts draining segment IVB arise, and yet further up the left duct are the ducts for segments II and III. These ducts can generally be found just posterior and lateral to the umbilical recess. The caudate lobe drains through smaller ducts that typically enter the right and left hepatic duct systems. In normal variant anatomy, there are two principal right hepatic duct systems (right anterior duct and right posterior duct) that join to form a short main right hepatic duct. The right anterior sectoral duct runs in a vertical direction to drain segments V and VIII, whereas the right posterior sectoral duct follows a horizontal course to drain segments VI and VII. In approximately 20% of patients the right posterior sectoral duct courses posterior to the right anterior duct to join the left hepatic duct. The right posterior duct in a small minority of patients has a lower entry point into the CBD making it susceptible to injury during cholecystectomy. The common variations in the main hepatic duct are depicted in Fig. 88.2.

The gallbladder is a partially intraperitoneal structure that lies attached to the undersurface of the liver on segments IVB and V. It is 7 to 10 cm in length; holds 30 to 60 mL of bile as a reservoir; and is divided into neck, infundibulum with Hartmann pouch, body, and fundus (see Fig. 88.1). On the side of the gallbladder that is attached to the liver, there is no peritoneal covering; a fibrous lining known as the *cystic plate* occupies this space. Bile is drained via a cystic duct to the CBD. The cystic duct can range from 1 to 5 cm in length and drains at an acute angle into the CBD. There are numerous variations in this insertion all along the length of the CBD, even including into the right hepatic duct (Fig. 88.3). The valves of Heister, which are folds of mucosa oriented in spiral pattern within the neck of gallbladder, function to retain bile in the gallbladder until contraction in response to enteric stimulation.

The common hepatic duct is anatomically defined as the segment of the extrahepatic bile duct below the biliary bifurcation and above the cystic duct insertion. Given the variability of the insertion of the cystic duct as described earlier, it is often more practical to divide the common duct system into proximal (within 2 cm of the bifurcation), distal CBD (coursing behind the duodenum and intrapancreatic), and mid-CBD (between the proximal and distal CBD segments). The distal CBD courses behind the first portion of the duodenum to enter into a groove on the posterior surface of the superior pancreatic head before joining the pancreatic duct and ending in the ampulla. The pancreatic duct also joins the ampulla, although in variants it may have a separate orifice (Fig. 88.4).

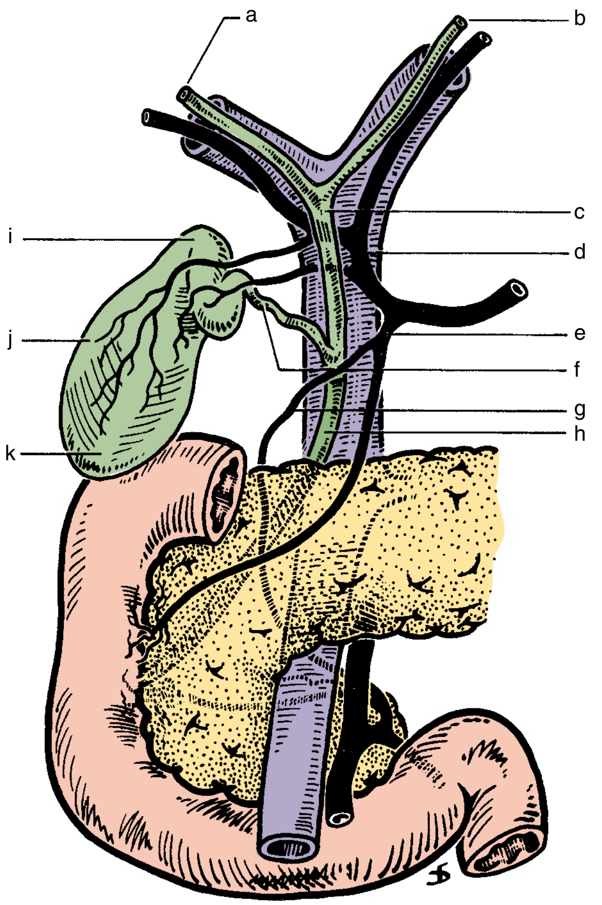

FIGURE 88.1 Extrahepatic biliary anatomy: *a*, right hepatic duct; *b*, left hepatic duct; *c*, common hepatic duct; *d*, hepatic artery; *e*, gastroduodenal artery; *f*, cystic duct; *g*, retroduodenal artery; *h*, common bile duct; *i*, neck of the gallbladder; *j*, body of the gallbladder; *k*, fundus of the gallbladder.

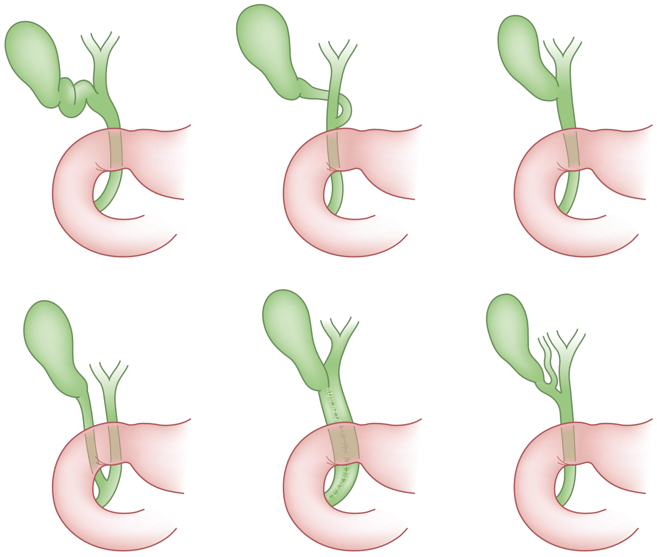

FIGURE 88.3 Variability in cystic duct anatomy. Knowledge of these variations is important to avoid inadvertent injury to the biliary tree during cholecystectomy.

Vascular Anatomy

As described by Couinaud,[1] the hepatic parenchyma is divided into lobes, each of which is divided into lobar segments to define the basic hepatic anatomic resections. The blood supply to the entire biliary tree is solely arterial in contrast with the hepatic parenchyma, where dual perfusion also comes from the portal vein, which makes the biliary tree susceptible to ischemic injury. The cystic artery normally arises from the right hepatic artery, and similar to the variability of the cystic duct, it may arise from the right hepatic, left hepatic, proper hepatic, common hepatic, gastroduodenal, or superior mesenteric artery. The cystic artery can pass posterior or anterior to the CBD to supply the gallbladder.

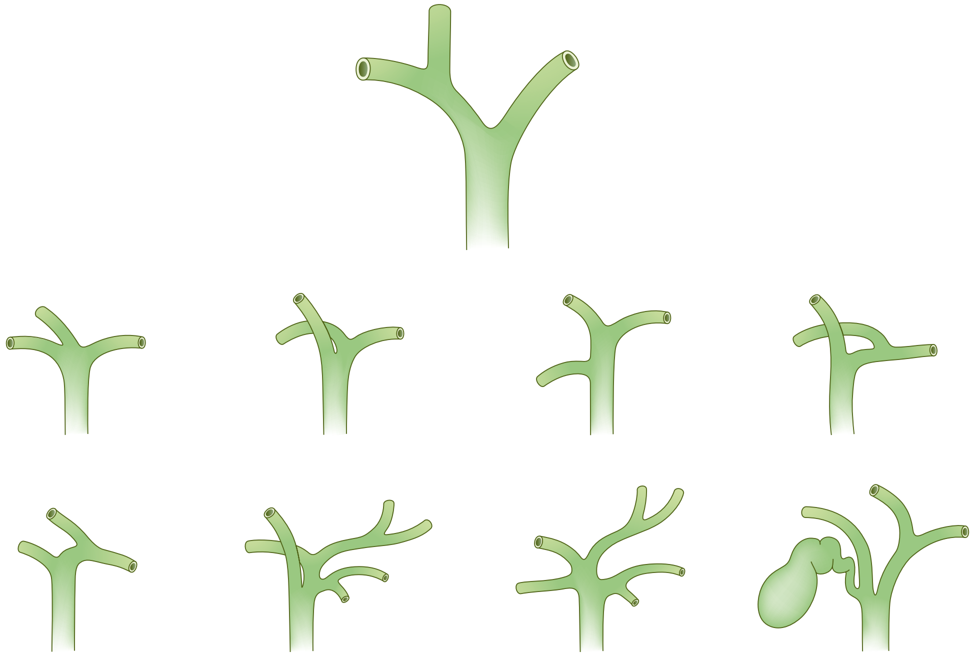

FIGURE 88.2 Variability in hepatic duct anatomy. Knowledge of these variations is important to avoid inadvertent injury to the biliary tree during liver resection.

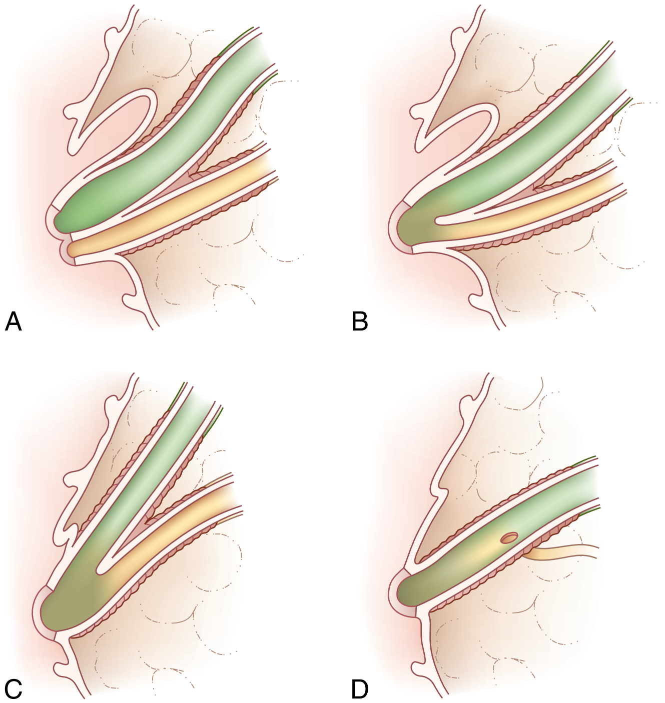

FIGURE 88.4 Patterns of biliary duct–pancreatic duct junction and insertion into the duodenal wall. (A) Separate common bile duct (CBD) and pancreatic duct (PD) entry. (B) Joining ducts at the ampulla. (C) Joining ducts before the ampulla. (D) PD entering the CBD.

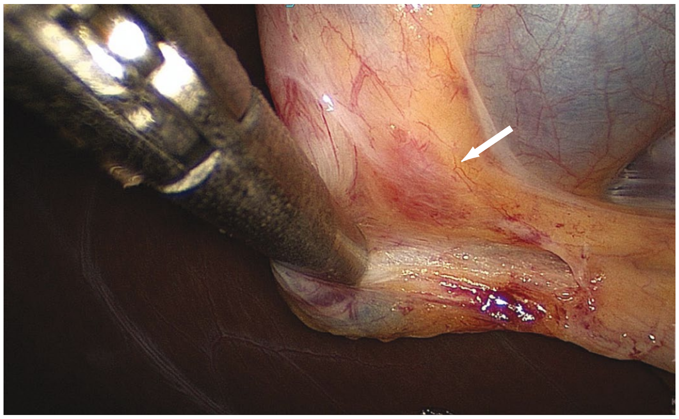

FIGURE 88.5 Operative photograph of Calot node. This node *(arrow)* is useful for identification of the common location of the cystic artery.

Although variable, the cystic artery generally lies superior to the cystic duct and is usually associated with a lymph node known as *Calot node* (Fig. 88.5). This node can be enlarged in the setting of gallbladder disease, whether inflammatory or neoplastic, because it provides the lymphatic drainage of the gallbladder.

The blood supply of the common hepatic duct and CBD comes from the right hepatic and cystic arteries. Typically, the right hepatic artery passes posterior to the common hepatic duct to supply the right lobe of the liver. It passes through the triangle of Calot (bordered by the cystic duct, common hepatic duct, and edge of the liver) after crossing the duct. The cystic artery takes off from the right hepatic artery in this triangle, which is at risk for injury during cholecystectomy. In performing a cholecystectomy, limiting the dissection to the right of the node of Calot helps minimize the risk of injury to the right hepatic artery and adjacent CBD.

It is important to remember that in 20% of the population, there is an accessory or replaced right hepatic artery passing through the portacaval space and ascending to the right lobe along the posterior and right lateral aspect of the CBD. A pulsatile structure palpated on the most lateral aspect of the porta during a Pringle maneuver identifies this anomaly. In addition, it can be noted on computed tomography (CT) as a vessel passing transversely between the portal vein and inferior vena cava behind the head of the pancreas.

The perfusion to the inferior bile duct, below the duodenal bulb, comes from tributaries of the posterosuperior pancreaticoduodenal and gastroduodenal arteries. The small branches coalesce to form the two vessels that run along the CBD at the 3- and 9-o'clock positions. These vessels can be damaged and leave the bile duct at risk for ischemic injury with close dissection of the areolar tissue surrounding the bile duct.

Physiology

The smallest functional unit of liver is the hepatic lobule. It is created by four to six portal triads and identified by its central terminal hepatic venule. Each hepatocyte is encircled by bile canaliculi, which coalesce to form small bile ducts. Bile salts, such as cholic acid and deoxycholic acid, are originally created from cholesterol and secreted into bile canaliculi as cholic acid and its metabolite, deoxycholic acid. The liver actually makes only a small amount of the total bile salt pool used on a daily basis because most bile salts are recycled after use in the intestinal lumen, known as the *enterohepatic circulation* (Fig. 88.6). Bile is secreted into canaliculi directly from hepatocytes. Once the bile components are secreted into the bile canaliculi, the tight junctions in the biliary tree keep these components within the bile secretory pathway. The secretion of bile components into the biliary tree is a major stimulus to bile flow, and the volume of bile flow is an osmotic process. Because bile salts combine to form spherical pockets, known as *micelles,* the salts themselves provide no osmotic activity. Instead, the cations that are secreted into the biliary tree along with the bile salt anion provide the osmotic load to draw water into the duct and to increase flow to keep bile electrochemically neutral. For this reason, bile maintains an osmolality approximately comparable to that of plasma.

After passage into the intestinal tract and reabsorption by the terminal ileum, bile acids are transported back to the liver for recycling bound to albumin. On the opposite side from the canalicular surface of the hepatocyte lies the sinusoidal surface, which contacts the space of Disse. In this contact area, the hepatocyte absorbs the circulating components of bile, an important step in the enterohepatic circulation. The passage of reabsorbed bile salts bound to albumin through the space of Disse allows uptake into the hepatocyte in an efficient process that involves sodium cotransport and sodium-independent pathways. In the less specific sodium-independent pathway, a number of organic anions are transported, including unconjugated and indirect bilirubin. The transport of bile salts across the canalicular membrane remains the rate-limiting step in bile salt excretion. Given the vast differences in concentration of bile salts, the transport of bile up an extreme concentration gradient is adenosine triphosphate dependent. Less than 5% of bile salts are lost each day in the stool. When sufficient quantities of bile salts reach the colonic lumen, the powerful detergent activity of the bile salts can cause inflammation and diarrhea. This can sometimes be seen after a cholecystectomy when the speed of the enterohepatic circulation of bile increases and may overwhelm the ability of the terminal ileum to absorb bile salts.

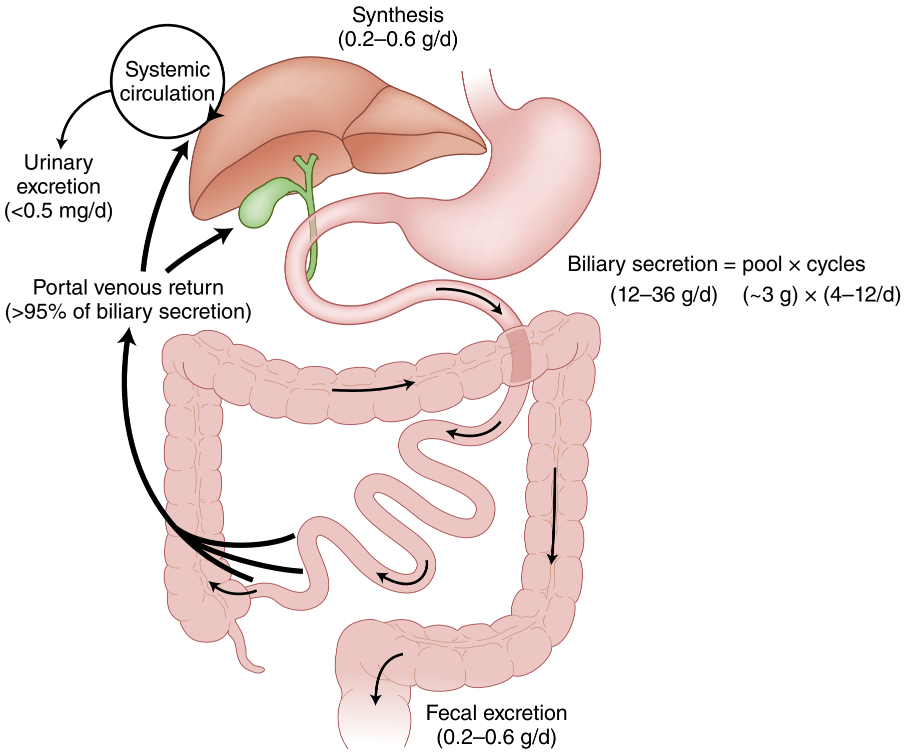

FIGURE 88.6 Enterohepatic circulation.

In addition to bile salts, bile contains proteins, lipids, and pigments. The major lipid components of bile are phospholipids and cholesterol. These lipids dispose of cholesterol from low- and high-density lipoproteins and serve to protect hepatocytes and cholangiocytes from the toxic nature of bile. The sources of most biliary cholesterol are circulating lipoproteins and hepatic synthesis. Therefore, the biliary secretion of cholesterol actually serves to excrete cholesterol from the body.

Aside from absorption of nutrients from the intestinal tract, bile secretion from the liver serves an opposing function, namely, excretion of toxins and metabolites from the liver. Bile pigments such as bilirubin are breakdown products of hemoglobin and myoglobin. These products are bound to albumin and transported in the blood to hepatocytes. Inside hepatocytes, they will be transferred into the endoplasmic reticulum and conjugated to form bilirubin glucuronides, known as *conjugated* or *direct* bilirubin. Bile pigment gives the color of bile and, when converted to urobilinogen by bacterial enzymes, gives stool its characteristic color.

Much of the bile flow is dependent on neural, humoral, and chemical stimuli. Vagal activity induces bile secretion as does the gastrointestinal hormone secretin. Cholecystokinin (CCK), secreted by the intestinal mucosa, serves to induce biliary tree secretion and gallbladder wall contraction, thereby augmenting excretion of bile into the intestines. Secreted bile will pass through the biliary tree into the intestine and be reabsorbed. The gallbladder serves as an extrahepatic storage site of bile, absorbing water and concentrating bile in an osmotic process performed through the active sodium transport. With the absorption of sodium and water across the gallbladder epithelium, the chemical composition of bile changes in the gallbladder lumen. Increases in cholesterol and calcium concentration lead to decreased stability of phospholipid cholesterol vesicles. The reduced vesicle stability predisposes to nucleation of this stagnant pool of cholesterol and, thus, to cholesterol stone formation. The gallbladder neck and cystic duct also secrete glycoproteins to help protect the gallbladder from the detergent activity of bile. These glycoproteins also promote cholesterol crystallization.

An increase in the activity of the sphincter of Oddi in the fasting state (Fig. 88.7), whose musculature is independent from the duodenal intestinal wall, increases pressure in the CBD, filling the gallbladder, which is capable of storing up to 300 mL of daily bile production, through a retrograde mechanism. This muscular sphincter normally maintains high tonic and phasic activity, which is inhibited by CCK. The passage of fat, protein, and acid into the duodenum induces CCK secretion from duodenal epithelial cells.

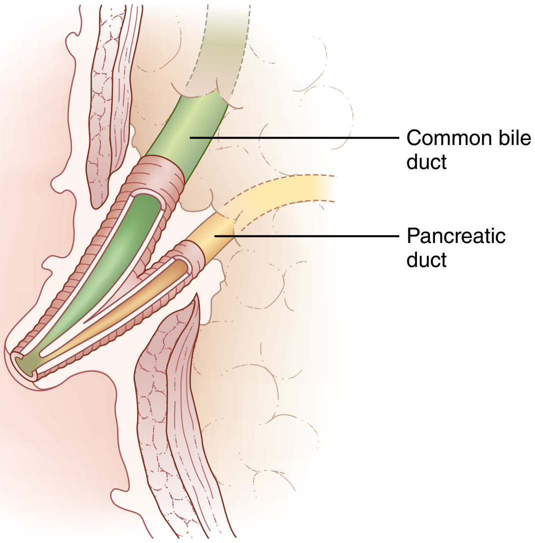

FIGURE 88.7 Sphincter of Oddi. Because the sphincter is responsible for control of most bile flow, this sphincter maintains a high tonic contraction but is inhibited by cholecystokinin.

CCK, as its name suggests, then causes gallbladder contraction, with intraluminal pressures up to 300 mm Hg. Vagal activity also induces gallbladder emptying but is a less powerful stimulus to gallbladder contraction than CCK. At the same time, CCK induces relaxation of the sphincter, causing bile flow more readily from the biliary tree. Coordinated with gallbladder contraction, the relaxation of this sphincter allows evacuation of up to 70% of the gallbladder contents within 2 hours of CCK secretion. During the fasting state, the oblique passage of the bile duct through the duodenal wall and the tonic activity of the sphincter prevent duodenal contents from refluxing into the biliary tree.

DIAGNOSTIC MODALITIES

Laboratory Tests

Laboratory studies are an integral part in the diagnosis and management of both benign and neoplastic pathologies. Both normal and abnormal results can illuminate the underlying disease process; however, it should be noted that there is no single laboratory test that can confirm or exclude a diagnosis, and adjunct tests including imaging should be considered.

Complete Blood Count

A complete blood count (CBC) is recommended for patients being evaluated for biliary disease. The diagnosis of cholecystitis is aided by the presence of leukocytosis, but it is not required. An elevated white blood cell count (WBC) serves as a systemic sign of inflammation, suggesting a diagnosis of acute cholecystitis or cholangitis when seen with biliary obstruction. When assessing the severity scores for a patient with acute cholecystitis, a WBC count of greater than 18,000/mm^3 is classified as grade II (moderate) acute cholecystitis per the 2018 Tokyo Guidelines and portends a worse prognosis.[2] In general, an elevated WBC in the setting of suspected biliary pathology should raise alarms.

Hepatic Function Panel

A hepatic function panel, or liver function test (LFT), investigates a number of metabolic and functional aspects of the liver and biliary system. Hyperbilirubinemia could be secondary to conjugated bilirubin, possibly due to obstruction, or secondary to unconjugated hyperbilirubinemia caused by increased synthesis, impaired hepatocyte uptake of unconjugated bilirubin, and decreased intracellular conjugation. Although this is an oversimplification of a complex process, derangements up to and including conjugation will be manifested as elevated unconjugated bilirubin levels. Elevation in serum bilirubin caused by obstruction of the biliary system will be identifiable first in the frenulum of the tongue, followed by the sclera (where the level of bilirubin must reach 2.5 mg/dL to be observed), and followed by the skin (minimum serum bilirubin of 5 mg/dL).

In cases of severe acute cholecystitis, pericholecystic and periductal inflammation can lead to mild elevations of total bilirubin (<3 mg/dL). Additionally, significant gallbladder distention can obstruct the extrahepatic biliary ducts leading to mild jaundice. The most common cause of biliary obstruction is choledocholithiasis, although Mirizzi syndrome, strictures, and malignancy should be considered in the differential.

Elevations in alkaline phosphatase (ALP) occur in response to cholestasis with minimal elevations in the parenchymal enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST). This pattern is referred to as a *cholestatic pattern,* as opposed to a *hepatocellular pattern,* which is suggestive of a hepatocyte physiology where the derangement is primarily an elevation in AST and ALT. However, it is important to note that significant elevations (especially elevated ALT) can be observed in some instances of biliary obstruction due to choledocholithiasis.

Unique Markers

Additional tests in the diagnosis of biliary diseases include gamma-glutamyl transferase (GGT), which can aid in the diagnosis of choledocholithiasis with a sensitivity and specificity of 90% and 85%, respectively.[3] Unlike the traditional LFTs, GGT levels increase earlier and persist longer in diseases that cause a cholestatic process, which makes it a potentially useful screening test. Carbohydrate antigen 19-9 (CA 19-9) is a tumor marker used in the diagnosis and prognostication of pancreaticobiliary malignancies. It can also be elevated in benign obstructions of the bile duct and should be interpreted with caution when suspecting a benign process.[4]

Imaging Studies

Plain Films

Historically, findings of pneumobilia, intestinal obstruction, and a stone in the right lower quadrant on abdominal x-ray (Rigler's triad) were pathognomonic for gallstone ileus. Plain radiographic films are of limited use in the overall evaluation of biliary disease as gallstones are not regularly observed by this modality. Therefore, the role of plain radiographs in the evaluation of biliary disease is limited to the exclusion of other diagnoses, such as a gastric or duodenal ulcer with free air, small bowel obstruction, or right lower lobe pneumonia causing right upper quadrant pain.

Ultrasound

Transabdominal ultrasound (US) is a sensitive, inexpensive, reliable, and reproducible test and is recommended as the first-choice imaging method for the initial evaluation of jaundice or symptoms of biliary disease. Although US has a high specificity and sensitivity for detecting gallstones (>95%), a meta-analysis revealed a sensitivity of 81% and specificity of 83% in the diagnosis of acute cholecystitis.[2] The gallbladder is easily evaluated by US due to its superficial location with no overlying bowel gas. The density of gallstones allows crisp reverberation of the sound wave, showing an echogenic focus with a characteristic shadowing behind the stone (Fig. 88.8). Most gallstones, unless impacted, will move promptly with positional changes in the patient. This characteristic allows their differentiation from gallbladder polyps, which are fixed in position, and from sludge, which moves more slowly, and do not have the sharp echogenic pattern of gallstones.

Pathologic changes of gallbladder disease can be identified by US. For example, the stigmata of cholecystitis includes gallbladder wall thickening and pericholecystic fluid, which are visible by US (Fig. 88.9). The sonographer may elicit a Murphy sign during the examination by pressing the probe into the right upper quadrant during inspiration eliciting cessation of inspiration. US can also assess dilation of the CBD in the setting of jaundice, which suggests obstruction of the duct and can be seen with choledocholithiasis, cholangitis, and malignant obstructions like cholangiocarcinoma (Fig. 88.10). Unlike a CT scan, US only provides a single slice view of the CBD, and therefore may underestimate CBD dilation. Rarely, a CBD stone may be visualized by US in the setting of choledocholithiasis.

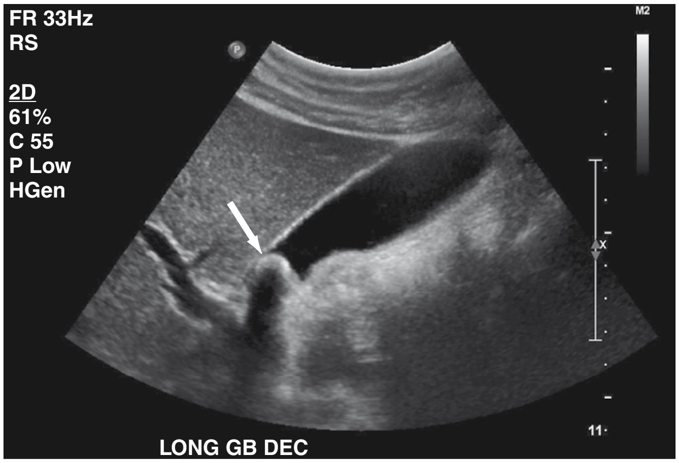

FIGURE 88.8 Ultrasound image of a gallstone in the gallbladder neck. The sharp echogenic wall of the gallstone *(arrow),* with the characteristic posterior shadowing stripe under the stone, helps differentiate it from other intraluminal findings.

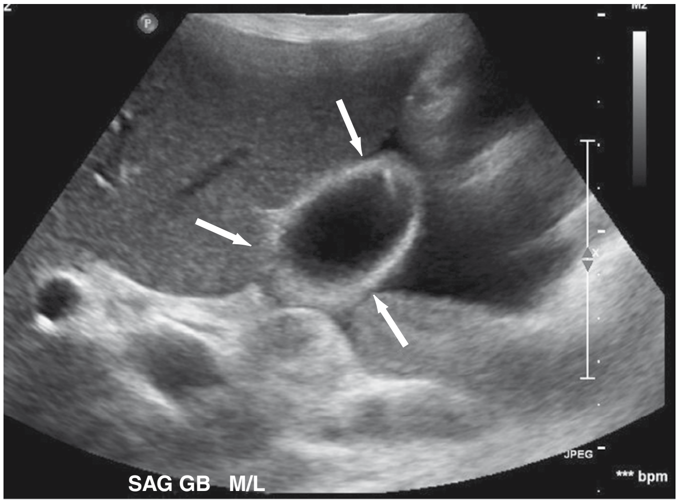

FIGURE 88.9 Ultrasound image with acute cholecystitis and thickened gallbladder wall *(arrows).*

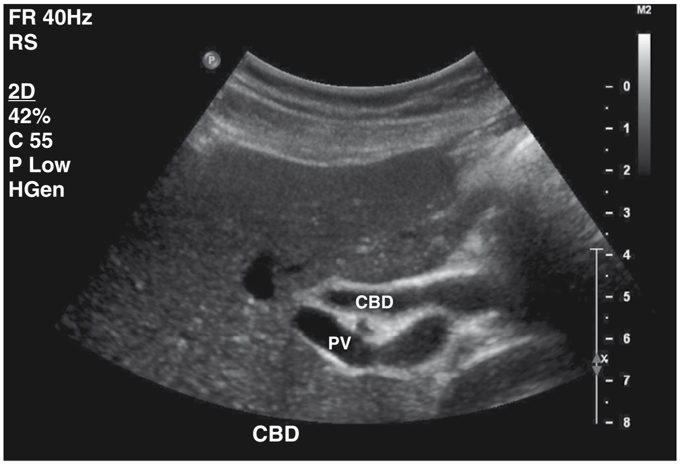

FIGURE 88.10 Ultrasound image of dilated biliary tree. The common bile duct *(CBD)* is dilated. As it travels parallel to the portal vein *(PV)*, it is easy to identify. The depiction of the parallel stripes of duct and vein helps ensure that the common duct diameter is not overestimated by a tangential view, which would artificially increase the anteroposterior diameter.

Computed Tomography

CT is an alternative imaging modality to evaluate biliary pathology. It provides superior anatomic detail given its ability to produce a high-resolution image of the surrounding anatomy. Because most gallstones are radiographically isodense to bile, many will be indistinguishable from bile. However, CT scans are more sensitive than US in the diagnosis of cholecystitis (90% vs. 80%).[5] As US provides no anatomic reconstruction of the biliary tree, CT can be used to identify the cause and site of biliary obstruction and is more sensitive when detecting ductal dilation seen with choledocholithiasis (Fig. 88.11).

CT should be strongly considered in the setting of obstructive jaundice when malignancy is suspected for the evaluation of hepatic and pancreatic parenchyma resulting in possible neoplastic processes. The addition of an arterial phase, portal venous phase, and delayed phase imaging, known as a *triple-phase CT*, is invaluable in preoperative planning for complex resections or reconstructions.

Cholescintigraphy

Although incapable of providing any precise anatomic delineation or ability to detect gallstones, cholescintigraphy, also known as a hepatic iminodiacetic acid (HIDA) scan, can be used to evaluate the physiologic secretion of bile. This test involves injection of the radiotracer iminodiacetic acid into the venous circulation, which is then processed in the liver and secreted into the biliary tree over several hours. Failure of the radiotracer to fill the gallbladder 2 hours after injection demonstrates obstruction of the cystic duct, as seen in acute cholecystitis, although false positives can occur in the fasting state (Figs. 88.12 and 88.13). Cholescintigraphy is extremely sensitive and specific (95% and 90%, respectively) for diagnosing acute cholecystitis. The HIDA scan can also help in confirming patency of the CBD and the presence of extraductal accumulation, indicating a leak of the biliary tree. Cholescintigraphy may also be useful in evaluating patients with biliary colic-type pain in the absence of stones. CCK is given during the

FIGURE 88.12 Hepatic iminodiacetic acid scan showing filling of the gallbladder. With gallbladder filling *(arrows)*, the diagnosis of acute cholecystitis is effectively eliminated.

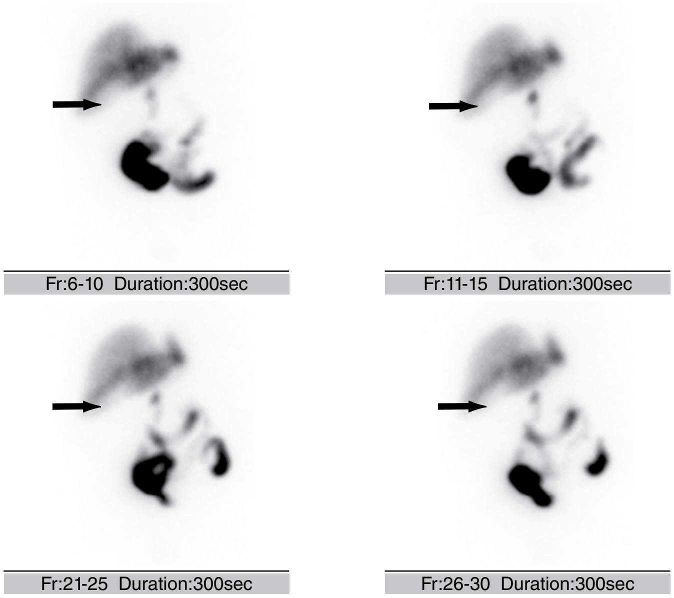

FIGURE 88.13 Hepatic iminodiacetic acid (HIDA) scan showing nonfilling of the gallbladder. With no filling of the gallbladder *(arrows)* even on delayed images, HIDA confirms occlusion of the cystic duct, the characteristic feature of acute cholecystitis.

scan to assess for physiologic ejection of the gallbladder, and a reduced ejection fraction (<35%) indicates impaired gallbladder emptying, known as *biliary dyskinesia.*

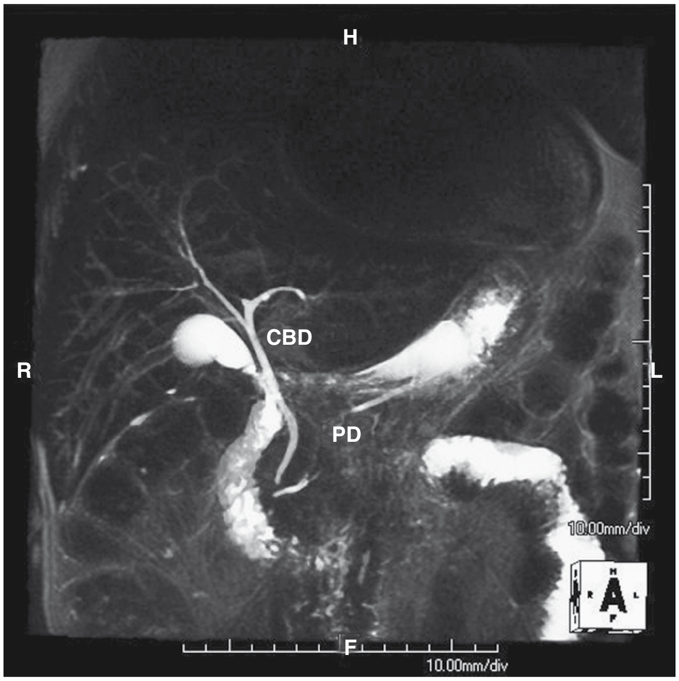

FIGURE 88.14 Normal magnetic resonance cholangiopancreatography image. Note the normal common bile duct *(CBD)* and pancreatic duct *(PD)*.

Magnetic Resonance Cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is an imaging modality introduced in the early 1990s as a noninvasive method to create a high-resolution image of the biliary system. It uses water in bile to delineate the biliary tree, thus providing superior anatomic definition of the intrahepatic and extrahepatic biliary tree and pancreas (Fig. 88.14). Unlike endoscopic retrograde cholangiopancreatography (ERCP), MRCP avoids ionizing radiation or an invasive procedure. For choledocholithiasis, it is a noninvasive option in patients with intermediate risk being considered for preoperative ERCP as it has significant diagnostic capacity (sensitivity of over 90% and specificity approaching 99%).[6] Its limitations include availability and inability to rule out a stone at the ampulla. This test is also useful in diagnosing and characterizing choledochal cysts, for planning resection of biliary or pancreatic neoplasms, and for the management of complex biliary disease.

Endoscopic Retrograde Cholangiopancreatography

ERCP, first described in 1968, is an invasive test using endoscopy and fluoroscopy to image the biliary tree (Fig. 88.15). A specialized endoscope with a side port is advanced into the duodenum to the ampulla of Vater. The ampulla is intubated, contrast is injected into the biliary tree, and fluoroscopic imaging is used to delineate biliary anatomy and identify biliary pathology. If stones are identified in the CBD, a sphincterotomy and/or sphincteroplasty may be performed with balloon sweeps to relieve obstruction. Although it does carry a complication rate of up to 10%, ERCP can diagnose and treat many diseases of the biliary tree and it has a greater than 90% stone clearance rate when treating choledocholithiasis. ERCP is also instrumental in the nonsurgical treatment of biliary duct injuries as the deployment of biliary stents diverts flow away from the injury to facilitate healing. For patients with a malignant obstruction, ERCP can provide tissue samples for diagnosis and temporize the obstruction with stenting. If biopsies are inconclusive and biliary malignancy remains highly suspected, retrograde cholangioscopy can be used to further evaluate the biliary tree and to obtain a tissue biopsy. When available, ERCP is a powerful tool in the treatment of biliary diseases.

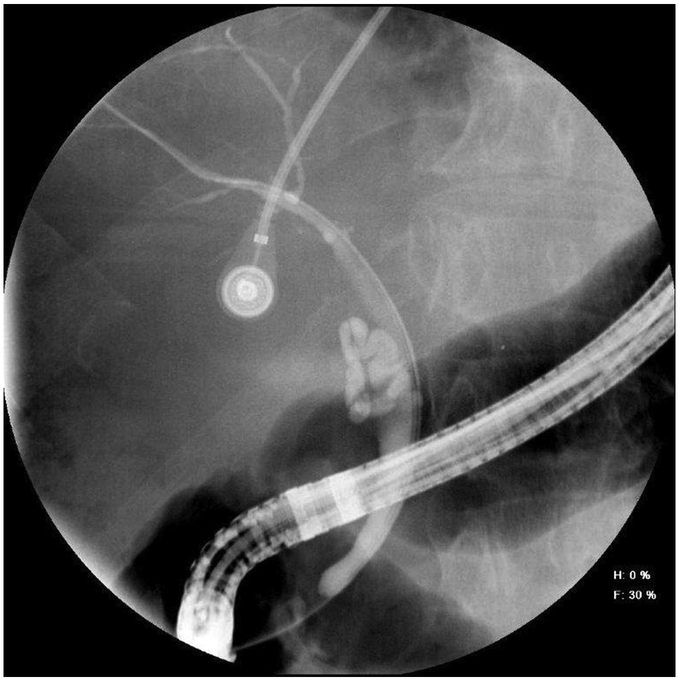

FIGURE 88.15 Normal endoscopic retrograde cholangiopancreatography image.

Endoscopic Ultrasound

Although of limited use in the evaluation of gallbladder disease or intrahepatic disease, endoscopic ultrasound (EUS) is a valuable tool to assess the distal CBD and ampulla. As it can be performed concurrently with ERCP, EUS is highly sensitive and specific (>95% and 90%, respectively) in the diagnosis of choledocholithiasis and can identify small and distal stones not seen on other imaging modalities such as MRCP.[7] It may also be used to assess neoplastic processes, including the degree of local invasion, in the distal biliary tree not well visualized with other techniques. Echoendoscopes are subdivided into those that scan perpendicular to the long axis of the endoscope, known as *radial echoendoscopes,* and those that scan parallel, known as *linear echoendoscopes.* Radial echoendoscopes are most useful for providing a tomographic evaluation, whereas linear echoendoscopes can guide interventions such as needle biopsies under real-time US guidance.

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (PTC) is an invasive radiologic procedure used to evaluate the biliary tree. Cannulation of the hepatic biliary ducts is performed by passing a needle percutaneously through the liver parenchyma into the biliary radicals under US guidance followed by contrast imaging of the biliary tree (Fig. 88.16). Image-guided access to the biliary tree can facilitate insertion of transhepatic catheters for drainage, biopsy, or stone extraction. This diagnostic and therapeutic technique can be instrumental in situations where decompression of the biliary tree is required and ERCP is not an option for anatomic, clinical, or resource reasons. However, in the setting of malignant obstruction and cholangitis, evidence suggests that endoscopic interventions have improved outcomes.[8]

Fluorodeoxyglucose Positron Emission Tomography

Fluorodeoxyglucose–positron emission tomography (FDG/PET) exploits the metabolic differences between a highly metabolically active tissue, such as a neoplasm, and normal tissue. With the injection of a radiolabeled glucose molecule, FDG/PET scans can help to differentiate benign and malignant lesions, detect recurrence, and identify metastatic disease. Unfortunately, given the relatively high background metabolic activity of the liver as well as the potential for false-positive activity in the setting of infection or inflammation, its role in the diagnosis of biliary track neoplasms is limited.

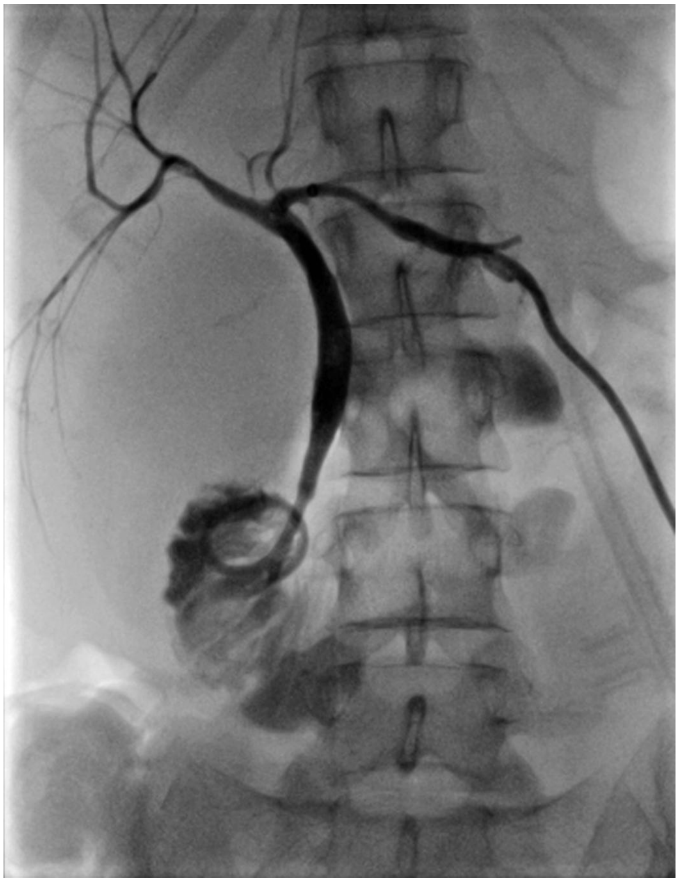

FIGURE 88.16 Percutaneous transhepatic cholangiography image of normal hepatic biliary anatomy.

Microbiology

The biliary tree inserts into the duodenum and is therefore not truly a sterile environment. Due to a low bacterial load and the flow of bile, infection in the absence of obstruction is rare, and the presence of stones or obstruction increases the likelihood of bacterial infection. There is a similarity in the microbiota of the duodenum and the biliary system, suggesting the bacteria that colonize the biliary tree arise from the upper enteric tract. Most bacteria isolated from the biliary tree are gram-negative or anaerobes. *Escherichia coli* followed by *Klebsiella* are the most common gram-negative bacteria isolated from the biliary tree and from blood cultures in cholangitis. The most common gram-positive bacteria associated with the biliary tract is *Enterococcus.*[9]

Biliary colic and choledocholithiasis do not have an infectious component to their pathology. Although cholecystitis is primarily an inflammatory process, cystic duct obstruction and biliary stasis can lead to a superimposed bacterial infection. Recommended regimens for antibiotic therapy include coverage for gram-negative bacteria and anaerobes, including piperacillin-tazobactam or a cephalosporin or fluoroquinolone with metronidazole for patients with a penicillin allergy. Even though there is no universally infectious process involved, the 2018 Tokyo Guidelines recommended antibiotic treatment before and at the time of cholecystectomy, whereas postoperative antibiotic use does not confer improved outcomes.[2]

BENIGN BILIARY DISEASE

Calculous Biliary Disease

Cholelithiasis is the most common disease of the gallbladder and biliary tree, affecting 10% to 15% of the population. Gallstones are generally classified into two major subtypes, cholesterol and pigment stones, depending on the principal solute that precipitates into a stone. More than 70% of gallstones in the United States are formed by precipitation of cholesterol and calcium, and pure cholesterol stones account for less than 10%. Pigment stones can be divided into black stones, as seen in hemolytic conditions and cirrhosis, and brown stones, which tend to be found in the bile ducts and are thought to be secondary to infection. The difference in color arises from incorporation of cholesterol into the brown stones. Because black pigment stones occur in hemolytic states from concentration of bilirubin, they are found almost exclusively in the gallbladder. Alternatively, brown stones can occur within the biliary tree and suggest a disorder of biliary motility and associated bacterial infection.

Four major factors explain most gallstone formation: supersaturation of secreted bile, concentration of bile in the gallbladder, crystal nucleation, and gallbladder dysmotility. High concentrations of cholesterol and lipid in bile secretion from the liver constitute one predisposing condition to cholesterol stone formation, whereas increased hemoglobin processing is seen in most patients with pigment stones. Once in the gallbladder, bile is concentrated further through the absorption of water and sodium, increasing the concentrations of the bile solutes and calcium. Bile salts act to solubilize cholesterol. With respect to cholesterol stones (Fig. 88.17), cholesterol precipitates out into crystals when the concentration in the gallbladder vesicles exceeds the solubility of cholesterol (Fig. 88.18).[10] Crystal formation is further accelerated by pronucleating agents, including glycoproteins and immunoglobulins. Finally, abnormal gallbladder motility can increase stasis in the gallbladder, allowing more time for solutes to precipitate in the gallbladder. Therefore, increased stone formation can be seen in conditions associated with impaired gallbladder emptying, such as in prolonged fasting states; with use of total parenteral nutrition; after vagotomy; with use of somatostatin analogues; and more recently with the use of GLP-1 receptor agonists for weight loss.[11]

Cholelithiasis is the most common disease of the gallbladder and biliary tree, affecting 10% to 15% of the population. Gallstones are generally classified into two major subtypes, cholesterol and pigment stones, depending on the principal solute that precipitates into a stone. More than 70% of gallstones in the United States are formed by precipitation of cholesterol and calcium, and pure cholesterol stones account for less than 10%. Pigment stones can be divided into black stones, as seen in hemolytic conditions and cirrhosis, and brown stones, which tend to be found in the bile ducts and are thought to be secondary to infection. The difference in color arises from incorporation of cholesterol into the brown stones. Because black pigment stones occur in hemolytic states from concentration of bilirubin, they are found almost exclusively in the gallbladder. Alternatively, brown stones can develop within the biliary tree and suggest a disorder of biliary motility and associated bacterial infection.

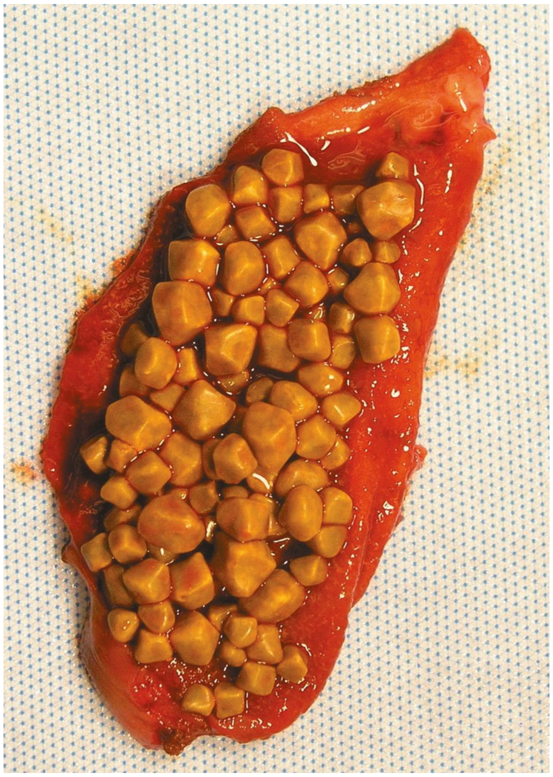

FIGURE 88.17 Gallbladder with characteristic yellow cholesterol stones.

Natural History

Gallstones become symptomatic when they obstruct a visceral structure such as a cystic duct. More commonly, gallstones remain asymptomatic and are only found incidentally on imaging. Biliary colic, caused by temporary blockage of the cystic duct, tends to occur after a meal in which the secretion of CCK leads to gallbladder contraction. Stones that do not obstruct the cystic duct or pass through the entire biliary tree into the intestines without impaction do not cause symptoms. Only 20% to 30% of patients with asymptomatic stones will develop symptoms within 20 years, and because approximately 1% of patients with asymptomatic stones develop complications of their stones before onset of symptoms, prophylactic cholecystectomy is not warranted in asymptomatic patients.[12]

Certain subsets of patients, however, constitute a higher risk pool, so prophylactic cholecystectomy may be considered. Among these are patients with hemolytic anemias, such as sickle cell anemia. These patients have an extremely high rate of pigment stone formation, and cholecystitis can precipitate a crisis. Patients with a calcified gallbladder wall (known as *porcelain gallbladder*) and those with large (>3 cm) gallstones have a potentially higher risk of symptomatic disease or conversion to cancer and should consider cholecystectomy. Also, in diabetic patients with gallstones, one should have a lower threshold for cholecystectomy, considering higher rate of gangrene.

In the era of open Roux-en-Y gastric bypass, there was a higher incidence of prophylactic cholecystectomy for asymptomatic cholelithiasis due to technical considerations and complications with

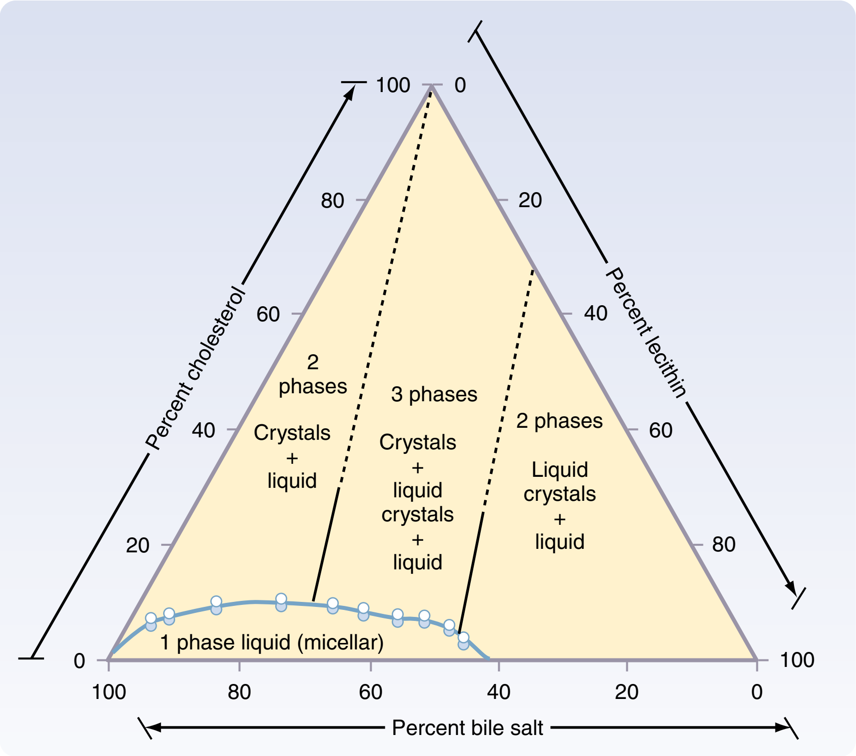

FIGURE 88.18 Triangle of solubility. With the three major components of bile that determine cholesterol solubility and stability, each can be quantified by molar percentage to show a relative ratio to the other two. Cholesterol is completely soluble in only the small area in the left lower corner, where a clear micellar solution exists, below the *closed circles.* Just above this, in the area between the *open* and *closed circles,* cholesterol is supersaturated but stable and thus crystallized only with stasis. In the remainder of the triangle, cholesterol is significantly supersaturated and unstable. In this region, crystals form immediately. (From Admirand WH, Small DM: The physicochemical basis of cholesterol gallstone formation in man. *J Clin Invest.* 1968;47:1043-1052.)

delayed cholecystectomy. There continues to be controversy over performing prophylactic concomitant cholecystectomy in patients undergoing minimally invasive bariatric surgery. In most cases, prophylactic cholecystectomy is not recommended. However, studies have shown that it is safe and effective for higher risk patients, or biliary colic patients, to have concomitant cholecystectomy at the time of metabolic bariatric surgery.[13] Rapid weight loss favors stone formation, but also, after gastric bypass, ERCP to remove CBD stones in ascending cholangitis can be challenging. Techniques for both laparoscopic and endoscopic management of CBD stones have improved over time, increasing success rates. Options for access to the biliary tree include laparoscopic-assisted access to the excluded stomach for which ERCP can be performed through a gastrotomy. Laparoscopic transcystic CBD exploration is described in detail later in the chapter. Newer endoscopic-only techniques include endoscopic stent placement between the pouch and gastric remnant to then perform ERCP through the stent (EUS-directed transgastric ERPC [EDGE procedure]).

Nonoperative Treatment of Cholelithiasis

Medical treatment of gallstones is mostly unsuccessful and includes oral bile salt therapy, contact dissolution that requires cannulation of the gallbladder and infusion of organic solvent, and extracorporeal shock wave lithotripsy. With the dissolution strategies, unacceptable recurrence rates of up to 50% limit their application to the most select group of patients. Extracorporeal shock wave lithotripsy has a lower recurrence rate, approximately 20%, and can be used in patients with single stones 0.5 to 2 cm in size. Newer modalities include cystic duct embolization with chemical ablation of the gallbladder; studies on these techniques have low patient volumes but prove to be safe for patients who are not operative candidates.[14] The widespread use, safety, and efficacy of laparoscopic cholecystectomy have relegated nonoperative therapy to patients for whom general anesthesia presents a prohibitively high risk.

Chronic Cholecystitis

Recurrent attacks of biliary colic, with only temporary occlusion of the cystic duct, can cause inflammation and scarring of the neck of the gallbladder and cystic duct. This process causes fibrosis as histologic evidence of repeated self-limited episodes of inflammation, resulting in chronic cholecystitis. The diagnosis of chronic cholecystitis lies along a continuum with biliary colic because it results from recurrent attacks. Therefore, the presentation is usually that of symptomatic cholelithiasis, or biliary colic. Pain occurring after ingestion of a fatty meal, with the attendant increase in CCK secretion in response to duodenal intraluminal fat, is classic for biliary colic, although only 50% of patients will report an association with food. Pain from stones tends to locate in the epigastrium or right upper quadrant and may radiate around to the scapula. These attacks of pain generally last a few hours. Pain lasting longer than 24 hours or associated with fever is more suggestive of acute cholecystitis. The pain of biliary colic, even in the absence of cholecystitis, may also cause other gastrointestinal symptoms, such as bloating, nausea, and vomiting.

Symptomatic stones constitute a risk profile different from that of asymptomatic stones, with a higher likelihood of complications including acute cholecystitis, choledocholithiasis, gallstone pancreatitis, cholangitis, and more. Therefore, symptomatic cholelithiasis is an indication for cholecystectomy. Documented stones and symptoms are the most common indications to perform a cholecystectomy.

Diagnosis

The diagnosis of chronic cholecystitis relies on a history consistent with biliary tract disease. Transabdominal ultrasonography reliably documents the presence of cholelithiasis. US can provide other important information, such as CBD dilation, gallbladder polyps, porcelain gallbladder, or evidence of hepatic parenchymal processes. Cholesterolosis, or the accumulation of cholesterol found in gallbladder mucosal macrophages, can also be seen. Gallbladder "sludge" or microlithiasis can be found on US and, with appropriate symptoms, is consistent with symptomatic cholelithiasis.

Treatment

Patients with sufficient symptoms from gallstones should undergo elective cholecystectomy. Cholecystectomy carries a low-risk profile but is not without complications, so an analysis of risks and benefits is important. Because patients with mild symptoms have a low rate of complications from gallstones (1%–3% per year), observation and dietary and lifestyle changes can be appropriate in this population, especially in the patient who does not wish to have surgery. Patients with more severe or recurrent symptoms have a higher rate of complications of the disease (7% per year), so elective laparoscopic cholecystectomy is warranted and encouraged. In more than 90% of patients, cholecystectomy is curative, leaving them symptom free.

Acute Calculous Cholecystitis

Acute calculous cholecystitis is the result of blocking the cystic duct with a gallstone. The blockage does not resolve spontaneously, leading to inflammation, edema, and subserosal hemorrhage. Continued cystic duct obstruction can lead to infection of stagnant bile and may progress to ischemia, necrosis, or gangrenous versus emphysematous cholecystitis. Patients presenting with acute cholecystitis experience symptoms of upper abdominal pain (right upper quadrant and/or epigastric) that lasts more than 4 to 6 hours. Often, careful history taking can elicit previous episodes of similar symptoms of shorter duration and less severe pain. Nausea and vomiting are often concomitant symptoms. Fever may also be present, but objectively occurs less frequently. The patient may have a known history of gallstones from previous episodes or incidentally from earlier imaging, focusing the diagnostic workup.

Diagnosis

The most common physical examination finding is right upper quadrant tenderness to palpation; an inflammatory mass may also be palpated, depending on body habitus. Inspiratory arrest with palpation over the gallbladder (Murphy's sign) is a classic physical finding. Alternatively, biliary colic in the absence of infection and inflammation is not associated with Murphy's sign. Despite these classic signs and symptoms, the presentation can be highly variable, especially in patients who are obese, diabetic, elderly, or immunosuppressed from various causes. There is also significant symptom overlap with other intraabdominal causes (e.g., peptic ulcer, gastritis, colitis).

Laboratory tests helpful in diagnosis are a CBC and complete metabolic profile including transaminases, ALP, and bilirubin. Mild elevations of ALP, bilirubin, and transaminase levels and leukocytosis support the diagnosis of acute cholecystitis. However, given that the CBD is not obstructed, profound jaundice in the setting of acute cholecystitis is rare and should raise the suspicion of cholangitis. Mirizzi syndrome should also be considered, in which inflammation or a stone in the gallbladder neck leads to inflammation of the adjoining biliary system causing obstruction of the common hepatic duct.

Imaging studies are standard in the diagnosis of cholecystitis. US, CT, HIDA, and MRI are all capable of diagnosing acute cholecystitis. Transabdominal ultrasonography is a sensitive, inexpensive, and reliable tool for the diagnosis of acute cholecystitis, with a sensitivity of 85% and specificity of 95%. In addition to identifying gallstones, US can demonstrate pericholecystic fluid, gallbladder wall thickening, and even a sonographic Murphy sign. US is therefore the diagnostic test of choice.

In atypical cases, or when ruling out other abdominal pathology, abdominal CT may be useful. CT is able to identify pericholecystic fluid, inflammation, and gallbladder thickening with high sensitivity. If the CT scan has characteristic findings, it is not necessary to perform an US even when stones are not radiographically visible. A HIDA scan may also be used to demonstrate obstruction of the cystic duct, which definitively diagnosis acute cholecystitis. Filling of the gallbladder during a HIDA scan eliminates the diagnosis of cholecystitis. MRI is highly sensitive for cholecystitis but is more expensive and less expeditious; therefore, it is typically reserved to rule out choledocholithiasis and malignancy when laboratory studies are suggestive of biliary obstruction.

There have been multiple grading systems evaluating severity of cholecystitis; the most widely used are the Tokyo Guidelines[15] and the American Association for the Surgery of Trauma (AAST) Emergency General Surgery (EGS) guidelines.[16] AAST EGS categorizes acute cholecystitis into five grades: Grade I is localized inflammation and grade V shows pericholecystic abscess, bilioenteric fistula, and peritonitis. The Tokyo Guidelines also grade the systemic effect of cholecystitis such as organ failure. Both classifications are helpful to categorize the management of these patients and consider treatment options relative to their severity of disease.

Treatment

In general, the ideal treatment for acute cholecystitis is cholecystectomy. However, treatment is often dependent on the severity of disease and the physiologic status of the patient. Therefore, treatment can vary from immediate surgical intervention to conservative management with interval cholecystectomy to nonoperative adjuncts. Patients with minimal medical comorbidity presenting early in the disease process should generally be managed with surgery. Those with significant, optimizable comorbidities but mild cholecystitis may merit a trial of medical therapy or "cool down" period followed by cholecystectomy after 6 to 12 weeks. Those who are critically ill or with severe comorbidities and severe acute cholecystitis are often best managed with early percutaneous cholecystostomy tube placement in conjunction with antibiotics and delayed cholecystectomy once their medical condition is satisfactory.

Although the primary pathophysiologic event in acute cholecystitis is the obstruction of the cystic duct and infection is a secondary event that follows stasis and inflammation, most cases of acute cholecystitis are complicated by superinfection of the inflamed gallbladder. Patients are given nothing by mouth, and intravenous (IV) fluids and parenteral antibiotics are started. Antibiotics are directed to treatment of common pathogens in bile cultures including *E. coli, Klebsiella, Enterobacter,* and *Bacteroides* species; broad-spectrum antibiotics are warranted. Parenteral narcotics are usually required to control the pain.

Cholecystectomy, whether open or laparoscopic, is the treatment of choice for acute cholecystitis. The timing of operative intervention in acute cholecystitis has long been, and continues to be, a source of debate. In the past, many surgeons advocated for delayed cholecystectomy with patients managed nonoperatively during their initial hospitalization and discharged home with resolution of symptoms. An interval cholecystectomy was then performed at approximately 6 weeks after the initial episode. More recent studies have shown that early in the disease process (within the first week), the operation can be performed laparoscopically with equivalent or improved morbidity, mortality, and length of stay as well as a similar conversion rate to open cholecystectomy.[17] In addition, approximately 20% of patients initially admitted for nonoperative management failed to respond to medical treatment before the planned interval cholecystectomy and required surgical intervention. No demonstrable difference is found in mortality rate, major bile duct injury, postoperative pain, or other significant complication in patients treated with early or delayed cholecystectomy. Multiple studies have shown the safety and efficacy of early, same-admission cholecystectomy in the management of cholecystitis.

Robotic cholecystectomy is an extension of the laparoscopic toolset and is preferred by some surgeons. Robotic port placement and technique is theoretically equivalent to laparoscopic cholecystectomy, as the robot is a laparoscopic device. Three-dimensional visualization and wristed instrument movement are described as advantages from frequent robotic users. Early studies suggested bile duct injury rates higher for robotic cholecystectomy than for laparoscopic approach, but meta-analyses of more recent studies have demonstrated similar outcomes except for longer operative times with the robotic approach.[18]

Indocyanine green (ICG) cholangiography during minimally invasive cholecystectomy (in both robotic and laparoscopic approaches) allows for real-time identification of biliary structures during cholecystectomy and in the current era is straightforward to perform. Selective intraoperative intraluminal contrast cholangiogram can also be useful in confirming difficult anatomy, and both modalities are discussed later.

Initial nonoperative therapy remains a viable option for patients who present in a delayed fashion or with prohibitive medical comorbidity and should be decided on an individual basis. If laparoscopic cholecystectomy is attempted, one must be prepared for significant inflammation in the porta hepatis. Early conversion to open cholecystectomy should be considered when delineation of anatomy is unclear; conversion to open rates approaches 10% is these cases. Alternatively, bailout options discussed later in this chapter may prove useful in the severely inflamed, difficult cholecystectomy.

For those patients in which up-front surgery is avoided, a course of antibiotics is attempted as "conservative" therapy. In the event of failed medical therapy, a percutaneously placed cholecystostomy tube may be necessary. Frequently performed with US or CT guidance under local anesthesia with some sedation, cholecystostomy can act as a temporizing measure by draining the infected bile. Percutaneous drainage results in improvement in symptoms and physiology, allowing a delayed cholecystectomy 3 to 6 months after medical optimization. In patients with cholecystostomy tubes, when fluoroscopy shows a patent cystic duct, the cholecystostomy tube can be removed and the decision for cholecystectomy determined by the patient's ability to tolerate surgical intervention. In patients who will not tolerate a general anesthetic due to severe medical comorbidity, interventional radiology (IR) or gastroenterology may offer long-term treatment options.[19] First, IR may be able dilate the drain tract and remove residual stones, then on a separate procedure date embolize the cystic duct followed by chemical ablation of the gallbladder. A gastroenterologist, on the other hand, may be able to perform transcystic drainage or transduodenal drainage of the gallbladder for long-term decompression. These options are not to be considered lightly and are reserved for the highest surgical risk patients.

Choledocholithiasis

Choledocholithiasis, or gallstones within the CBD, is present in up to 20% of patients with cholelithiasis. Primary choledocholithiasis refers to de novo stone formation in the CBD and are usually brown pigmented stones due to a combination of precipitated bile pigments and cholesterol. Brown pigment stones, more common in Asian populations, are associated with bacterial infections where free bilirubin is formed by hydrolyzing enzymes released by bacteria and then precipitates forming a stone. Secondary choledocholithiasis, more commonly seen in the United States, is characterized by cholesterol or pigmented stones formed in the gallbladder that escape from the gallbladder into the CBD. Retained stones, which occur in 1% to 2% of patients, refer to secondary stones identified in the CBD within 2 years after cholecystectomy (Fig. 88.19).

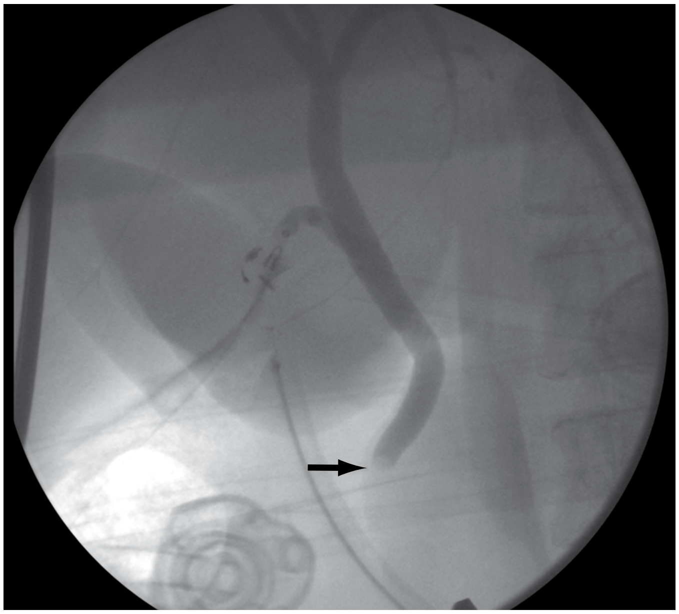

FIGURE 88.19 Intraoperative cholangiogram showing choledocholithiasis in an asymptomatic patient with no filling of duodenum and outline of stone *(arrow)*.

Diagnosis

When symptomatic, clinical manifestations of common duct stones range from biliary colic to signs of obstructive jaundice, including darkening of the urine, scleral icterus, and lightening of the stools. Jaundice with choledocholithiasis is more likely to be painful because the onset of obstruction is acute, causing rapid distention of the bile duct and activation of pain fibers. The presence of pain is an important distinguishing factor between choledocholithiasis and malignant obstructions.

Although asymptomatic choledocholithiasis is usually an incidental finding, biliary type pain, jaundice, an abnormal liver function panel indicating cholestasis, and a dilated bile duct (usually more than 8 mm) are all highly suggestive of choledocholithiasis. Although certain laboratory derangements can suggest a diagnosis of choledocholithiasis, there are no specific lab findings that are pathognomonic for the diagnosis. An elevated total bilirubin carries a low sensitivity but a high specificity for choledocholithiasis. When elevated bilirubin is seen in conjunction with an abnormal US, the pretest probability of finding choledocholithiasis approaches 90%, whereas a patient with a normal US and LFTs has a probability of <5% for choledocholithiasis.[20] Elevations in AST, ALT, and ALP are also useful, but no consensus exists regarding their cutoff values. In general, LFTs should not be relied upon as the sole predictor for choledocholithiasis and the overall clinical picture with radiographic findings should be considered when diagnosing choledocholithiasis.

Other laboratory findings can suggest pathologies that are associated with choledocholithiasis. Leukocytosis, especially with other signs of systemic inflammatory response, warrants concern for cholangitis. Epigastric pain elicited on examination should also raise suspicion for concomitant pancreatitis and serum lipase levels should be investigated. Elevations in lipase greater than three times the upper limit of normal are diagnostic for pancreatitis. Dilation of the CBD on US is suggestive of choledocholithiasis, and in some cases an actual stone in the CBD can be visualized. US is more specific than sensitive for diagnosing choledocholithiasis, with values of roughly 90% and 80%, respectively. The cutoff value for CBD dilation in the average adult is greater than 5 to 6 mm. Normal CBD dilation can be seen in patients after cholecystectomy due to reservoir effect and in the elderly due to normal dilation related to age. In patients over 65 years old, a CBD greater than 8 mm is typically considered abnormally dilated. It is important to note that overreliance on ductal dilation may underestimate the presence of choledocholithiasis given the variation in technician skills and the single view of the duct generated by US. Furthermore, lack of CBD stone visualization on US does not rule out choledocholithiasis in patients with other findings consistent with the disease.

Although CT is not necessary for the diagnosis of choledocholithiasis, it is often obtained as part of a workup for abdominal symptoms and is highly sensitive with values upward of 90% versus 80% of US. Additionally, it gives a full anatomic view of the biliary system, pancreas, and liver and may identify anatomic or vascular anomalies, which can be advantageous for preoperative planning. Unlike the previous tests typically ordered when patients are first evaluated in the emergency department, MRCP is used as an ancillary test for the diagnosis of choledocholithiasis. MRCP is highly sensitive (>90%) and specific (>99%) in identifying CBD stones (Fig. 88.20). Limitations of MRCP are in its ability to detect small stones (i.e., <6 mm) in the distal duct or those impacted in the ampulla. As it only serves as a noninvasive, diagnostic test, a therapeutic procedure, such as ERCP or CBD exploration (CBDE), is still required once the diagnosis in confirmed. When the operating surgeon does not have the technical skill or equipment to perform a CBDE at the time of cholecystectomy, and there is a moderate likelihood for choledocholithiasis, MRCP can aid in the decision to perform a preoperative ERCP.

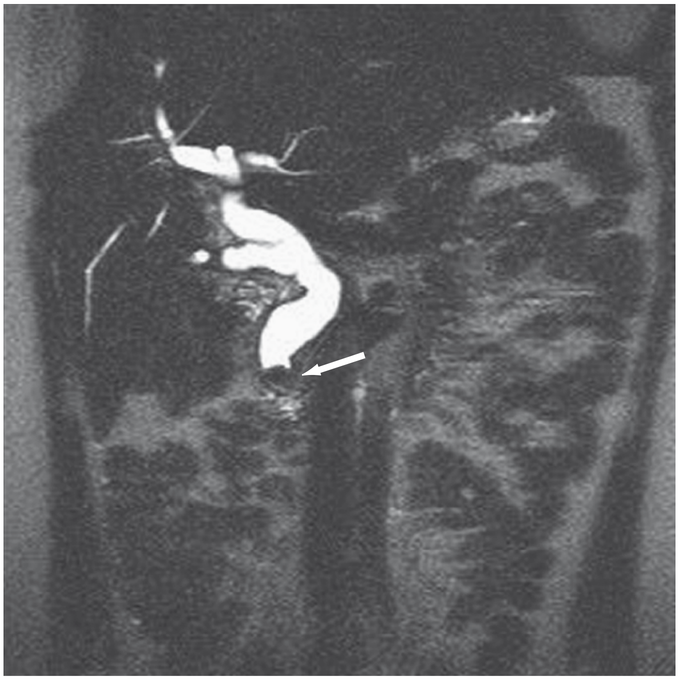

FIGURE 88.20 Magnetic resonance cholangiopancreatography with choledocholithiasis. The dilated common bile duct ends abruptly with a convex intraluminal filling defect *(arrow)* consistent with choledocholithiasis.

ERCP is also highly sensitive and specific for choledocholithiasis (Fig. 88.21). It is often the therapeutic procedure used to clear the duct in more than 75% of patients during a first procedure and in 90% with repeated ERCP. A sphincterotomy with a balloon sweep is performed and stones are extracted, with a complication rate including pancreatitis of up to 10%. Indications for preoperative ERCP include cholangitis, ongoing biliary pancreatitis, and patients with multiple comorbidities that are high risk for surgery. However, some studies have suggested higher risk of surgical site infection in patients who receive preoperative ERCP before cholecystectomy.[21]

Findings of choledocholithiasis via intraoperative cholangiogram during cholecystectomy may be managed by either CBDE or postoperative ERCP. The use of CBDE exploration by surgeons has dramatically declined with the advent of laparoscopic surgery and with concomitant advances in endoscopy. However, it is a safe and feasible procedure with similar duct clearance rates to ERCP and will be discussed in the next section as a one-stage management for choledocholithiasis.

PTC can also be used to treat choledocholithiasis in case of unsuccessful ERCP or in the setting of anatomic difficulty for ERCP such as a previous history of Roux-en-Y gastric bypass. PTC is as effective as ERCP in patients with a dilated biliary system with similar complication rate, but less effective and more technically challenging in patients without intrahepatic ductal dilation.

Treatment

Treatment for choledocholithiasis is generally ERCP or CBDE, which can be performed via robotic-assisted laparoscopic, laparoscopic, or

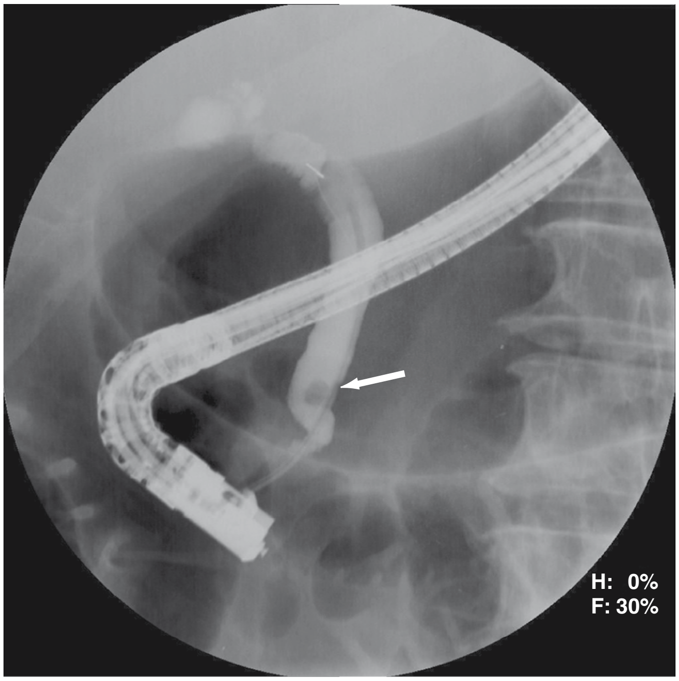

FIGURE 88.21 Endoscopic retrograde cholangiopancreatography (ERCP) with choledocholithiasis. With retrograde injection of contrast material, a filling defect noted within the lumen of the common bile duct *(arrow)* identifies choledocholithiasis. ERCP can also be used to remove the stone through sphincterotomy and balloons or baskets.

open technique. In patients with a low index of suspicion, a laparoscopic cholecystectomy can be performed with an intraoperative cholangiogram to confirm that the duct is clear of stones. In patients with a high index of suspicion, the surgeon should proceed with a plan to clear the duct. This can be done via a preoperative or postoperative ERCP or via a laparoscopic CBDE (LCBDE) with cholecystectomy. For patients with moderate risk for choledocholithiasis, the order of intervention may vary based on institutional policies and ERCP availability. Several medical societies have created algorithms to assist physicians in the diagnosis and management of choledocholithiasis, including the American Society for Gastrointestinal Endoscopy (ASGE)[22] and Society of American Gastrointestinal and Endoscopic Surgeons (SAGES).[6]

In the preoperative setting, endoscopic sphincterotomy with stone extraction by ERCP is effective for the treatment as it can clear the duct of stones. Because more than half of patients managed by ERCP without cholecystectomy will have recurrent symptoms of biliary tract disease, same-admission cholecystectomy is advised. When initial ERCP is unsuccessful at removal of all stones, a stent can be placed to temporize the obstruction and allows for serial attempts at duct clearance. Large stones (usually more than 2.5 cm), altered gastric or duodenal anatomy such as Roux-en-Y, impacted stones, intrahepatic stones, or multiple stones are the most common causes of ERCP failure. In these cases, operative CBDE, laparoscopic-assisted ERCP, or PTC drain placement to alleviate duct obstruction should be considered. With the advancement of technology for choledochoscopy that can be used as an adjunct to ERCP, PTC, or intraoperatively, visualization of the bile duct with options for lithotripsy and stone retrieval are more frequently employed in the management of complex choledocholithiasis.

Acute Cholangitis

Cholangitis, first described by Jean Martin Charcot in 1877, is an ascending infection of the CBD secondary to obstruction and increased intraluminal pressure. The classic Charcot triad of fever, jaundice, and right upper quadrant pain can be seen in less than 50% of all patients, with jaundice as the least common finding. Leukocytosis with an abnormal liver panel is more common. Hepatocellular injury from the infection and inflammation elevate serum transaminase and ALP levels. Symptoms may progress to septic shock with mental status changes, and hypotension (known as *Reynolds pentad*), which is an ominous sign, and mortality approaches 100% without prompt treatment.

Any obstructing phenomenon, from stones to neoplasms, can cause ascending bacterial infection of the biliary tree, but choledocholithiasis is the most common cause. A compelling reason to treat choledocholithiasis early is the risk of developing cholangitis, which is upward of 5% in admitted patients with choledocholithiasis. With obstruction from a stone, bactibilia can be identified in up to 90% of patients. The most common pathogens include *Klebsiella*, *E. coli*, *Enterobacter*, *Pseudomonas,* and *Citrobacter* spp.

US should be the first screening test and will commonly show dilation of the biliary tree. HIDA scans should be interpreted with caution because infection of the biliary tree reduces the secretion of these agents into the biliary tree. CT can be helpful in identifying the site of obstruction, although it is not always the case. The most valuable modalities are cholangiography through ERCP or PTC as they are not only diagnostic but also therapeutic.

Once the diagnosis of cholangitis is confirmed, the severity of the disease should be assessed, and adequate hydration and IV antibiotics should be started immediately. For patients with mild acute cholangitis, treatment with antibiotics alone is usually sufficient, but there should be a low threshold for immediate biliary drainage if the patient does not respond to initial treatment. For moderate acute cholangitis, early duct clearance via endoscopic or percutaneous techniques should be employed. For severe acute cholangitis, the patient will require stabilization of their acute hemodynamic and respiratory conditions followed by prompt biliary drainage.[23] Most patients will improve with medical therapy and either endoscopic or percutaneous biliary drainage. If endoscopic and percutaneous means are unavailable or unsuccessful, surgical drainage consists of common duct exploration with placement of a T-tube. Given the unstable nature of the patient, definitive surgical treatment of the cause is deferred until the patient is stabilized, the cholangitis is treated, and the diagnosis is confirmed.

Gallstone Pancreatitis

Gallstones are the most common cause of pancreatitis in the Western world and are present in 45% of cases.[24] When a stone passes from the bile duct through the ampulla into the duodenum, this may cause secondary injury to the pancreas. Temporary elevation of the pancreatic duct pressure causes inflammation and may result in severe pancreatic injury. Symptoms usually persist even after passage of the stone. US usually shows gallstones, choledocholithiasis, or a dilated CBD. The offending stone usually passes spontaneously, but the injury still can be severe. In most cases of gallstone pancreatitis, the pancreatic inflammation is self-limited. Early ERCP to remove a stone that may not have passed is indicated only for patients with concomitant cholangitis or complications from ongoing biliary obstruction. To prevent a future episode of gallstone pancreatitis, a cholecystectomy is warranted before discharge for mild to moderate cases and cholecystectomy should be delayed for patients with severe or complicated disease including necrotizing pancreatitis. Multiple studies have demonstrated that cholecystectomy within 2 days of admission was safe for patients with mild disease.[25] Given the suspicion of choledocholithiasis, intraoperative cholangiography should be performed at the time of cholecystectomy to confirm the passage of stones.

Gallstone Ileus

A misnomer, gallstone ileus is in fact a mechanical intestinal obstruction secondary to a gallstone. It occurs when a large stone in the dependent portion of the gallbladder fistulizes into the adjacent duodenum, passing directly into the intestine. This usually happens in older patients and can be caused by inflammation or pressure necrosis. The most common site for obstruction is in the terminal ileum before entering the cecum (Fig. 88.22) but can also occur in the duodenum leading to a gastric outlet obstruction called *Bouveret syndrome*.

Diagnosis

The common presentation for gallstone ileus is an elderly patient with some history of biliary tree disorder, with no past surgical history or hernia, who presents with a sudden mechanical small intestine obstruction.

Although most patients will have constant pain from the obstruction, others can present with only episodic discomfort because the gallstone only intermittently obstructs the intestinal tract. Historically, the diagnosis of gallstone ileus was made on plain abdominal film. The pathognomonic findings of pneumobilia from the fistula, signs of a high-grade small bowel obstruction, and a radiopaque stone in the right lower quadrant is called Rigler's triad. More often, emergency departments will perform an abdominal CT, which will still show these findings but with better anatomic detail. Pneumobilia, which may sometimes be identified only by CT scan, is a ubiquitous finding because the fistula that permitted a stone to pass into the duodenum allows air to enter the biliary tree.

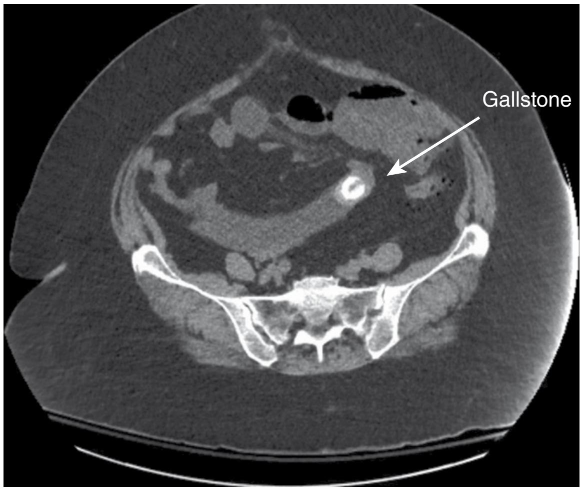

FIGURE 88.22 Computed tomography scan of stone *(arrow)* obstructing the distal ileum.

Treatment

Gallstone ileus is a surgical disease. Once the site of obstruction is identified, a longitudinal incision on the antimesenteric border of the ileum is made a few centimeters proximal to the stone. This site of impaction is at risk of perforation, so signs of ischemia may mandate resection. The stone is milked back through the enterotomy. Approximately 10% of patients have multiple large stones. Therefore, palpation of the remaining small intestine should be performed to exclude a second stone that could cause recurrent obstruction.

Concomitant cholecystectomy should be avoided at the time of stone extraction given the underlying intense inflammatory process that leads to formation of the biliary enteric fistula in the first case. Furthermore, because most of these patients are older, their overall physiologic status may not permit fistula repair in the emergent setting. One-stage repair should be reserved for healthy patients without severe inflammatory changes in the right upper quadrant. For patients with recurrent symptoms, an interval cholecystectomy can be considered to avoid the possibility of future biliary complications.

Noncalculous Biliary Disease

Acute Acalculous Cholecystitis

Blockage of the cystic duct in the absence of gallstones is called acalculous cholecystitis. The pathogenesis of acalculous cholecystitis is poorly understood, but is likely the result of biliary stasis, distention, inflammation, and ultimately superimposed infection and gangrene. Risk factors include old age, burns and trauma, prolonged use of *total parenteral nutrition,* critical illness, immunosuppression, and diabetes, and the presentation can be similar or more fulminant than calculous cholecystitis and may progress to gangrenous gallbladder. Critically ill patients with acalculous cholecystitis may not have right upper quadrant pain or any fever with unknown origin in critically ill patients, especially with pericholecystic fluid and gallbladder wall thickening on imaging, which should raise suspicion for this disorder. HIDA scan is diagnostic for acalculous cholecystitis but can have false-positive result.

Treatment of acalculous cholecystitis is similar to that of calculous cholecystitis, with cholecystectomy being therapeutic. However, unlike calculus cholecystitis, this disease process occurs in some of the most critically ill patients who are unable to tolerate surgical intervention and often require nonoperative strategies. Therefore, percutaneous cholecystostomy tube placement under imaging to drain the gallbladder is a much safer option. More than 90% of these patients improve with a cholecystostomy tube, and interval cholecystectomy is necessary only if follow-up imaging continues to demonstrate the positive findings. In the rare situation in which a patient undergoes a percutaneous cholecystostomy tube placement and fails to improve after 24 hours, exploration with cholecystectomy should be considered because these patients are likely to have perforated and drainage alone will be insufficient.

Biliary Dyskinesia

Biliary dyskinesia is a functional disorder of the biliary tree, generally defined by gallbladder dysmotility. Many hypotheses have been proposed, and it likely involves a malfunction in the normal motility response that leads to symptoms of biliary colic without cholelithiasis. It is usually a diagnosis of exclusion. Patients may present with classic symptoms of biliary colic but have no ultrasonographic evidence of stones or sludge. More vague symptoms, including nausea and oral intolerance, may also be present.

A confounding factor in these patients is that they often have other functional disorders including delayed colonic transit and gastric emptying. Thus, the amalgamation of symptoms may sometimes delay the diagnosis of these patients. The Rome foundation was developed with a mission to help diagnose and treat functional gastrointestinal disorders. They developed a diagnostic criterion to help rule out other frequent causes including gastroesophageal reflux disease (GERD) and inflammatory bowel syndrome.[26] Additional tests to help evaluate for other diagnoses include CT and endoscopy. Cholescintigraphy can be a useful tool in the diagnosis of biliary dyskinesia. The dysmotility of the gallbladder can be identified during a CCK-stimulated HIDA scan. The CCK stimulates the gallbladder to contract and an ejection fraction can be estimated. An ejection fraction less than ~35% is considered suggestive of biliary dyskinesia. More than 85% of patients show improvement in symptoms after cholecystectomy. Factors that predict a better response to cholecystectomy are typical biliary colic symptoms and a reduced ejection fraction. However, these do not guarantee a response. In patients with atypical symptoms, such as nausea as the primary symptom, response to cholecystectomy is less beneficial. In nonresponders, ERCP with sphincterotomy may prove useful.

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction (SOD) is a rare but clinically significant disease presentation. It is caused by a structurally or physiologically abnormal sphincter with higher tone and failure to relax, manifested by pain, and recurrent pancreatitis with a usually normal liver function panel. Risk factors include chronic pancreatitis or calculous disease, which can cause fibrosis due to inflammation, and, subsequently, failure of the sphincter to relax.

The disease's etiology is a failure of the sphincters to relax, increasing the pressures of the biliary tree. The two major types of disease presentations are the biliary and pancreatic subtypes. As the name suggests, the biliary subtype will present with classic biliary colic symptoms, whereas the pancreatic subtype will present with recurrent pancreatitis. The diagnosis of SOD should be suspected in patients with biliary pain and a common duct diameter of more than 12 mm. The bile duct in these patients tends to increase in diameter in response to CCK, as does the pancreatic duct after secretin administration. Initial diagnosis can be assisted through the presence of certain criteria. One of the most widely used is the Milwaukee classification.[27] Type I SOD has typical pain, abnormal pancreatic or hepatic enzymes, and CBD dilation. This is the most likely to respond to intervention. Type II has pain in addition to one of the other criteria. Type III has pain only and is the least likely to respond to intervention.

The intervention for SOD is ERCP with sphincterotomy and is highly effective with up to 90% resolution in symptoms. During ERCP, sphincter manometry can be performed and a pressure greater than 40 mm Hg is consistent with the diagnosis. However, manometry is not widely done as it is an invasive procedure that brings a real risk of pancreatitis. The successful use of botulinum toxin on the muscles of the sphincter predicts responsiveness to sphincterotomy. However, if nonprocedural interventions are desired, treatment with nitrates and calcium channel blockers have been attempted with moderate success.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an idiopathic disorder and considered an autoimmune process affecting the biliary tree. PSC is associated with other autoimmune disorders such as ulcerative colitis (in almost 70% of patients) and Riedel thyroiditis.[28] PSC can be categorized into four anatomic subtypes depending on the level of biliary tree it involves, including intrahepatic, extrahepatic, combined, or small ducts disease. The course of PSC is characterized by progressive chronic cholestasis and advances at an unpredictable rate to biliary cirrhosis and eventually death from liver failure. With improved understanding of the disease and early diagnosis, PSC outcomes have improved.

Clinical presentation. Most patients present with general symptoms such as fatigue and pruritus, but abnormal liver function studies are usually what prompts biliary imaging. Approximately 80% of patients have elevated perinuclear antineutrophil cytoplasmic antibodies, but the severity of disease does not correlate to titer levels. Abnormal LFTs in a patient observed for inflammatory bowel disease should suggest PSC.

Imaging with cholangiography demonstrates a multifocal diffuse dilation and stricturing of the intrahepatic and/or extrahepatic biliary trees. This pattern is called *beading* or *chain of lakes* and is characteristic of PSC. MRCP is useful in the diagnosis and surveillance of PSC patients, whereas ERCP is reserved for the treatment of dominant strictures and to exclude malignancy, namely, cholangiocarcinoma (Fig. 88.23).

Liver biopsy tends to show an onionskin concentric periductal fibrosis. With disease progression, periportal fibrosis occurs, progressing to bridging necrosis and, eventually, biliary cirrhosis. Unfortunately, PSC is associated with cholangiocarcinoma, and distinguishing the strictures of PSC fibrosis from those of cholangiocarcinoma can be challenging.

Treatment. Ursodeoxycholic acid is commonly used as medical therapy for PSC and has demonstrated some improvement in LFTs; however, it is controversial whether this alters the progression of disease. Ongoing trials in PSC include ursodeoxycholic acid homologs, antibiotics to alter the microbiome, and interruption of the enterohepatic bile circulation. However, none of these agents has shown a consistent clinical benefit. In the symptomatic patient, endoscopic therapy, consisting of balloon dilation of the dominant strictures, has been shown to alleviate pruritus, to reduce likelihood of cholangitis, and even to prolong survival.

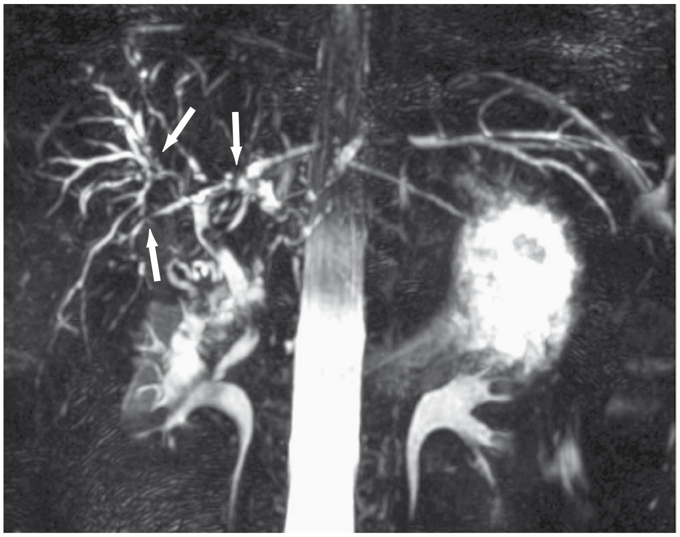

FIGURE 88.23 Magnetic resonance cholangiopancreatography showing primary sclerosing cholangitis. Note the multilevel strictures *(arrows)*.

Surgical treatment options include biliary reconstruction in symptomatic patients with focal extrahepatic disease in some cases. Such patients are rare, and repeated operations for drainage have been shown to complicate definitive treatment by liver transplantation. Therefore, the use of biliary reconstructive procedures has decreased for this indication. Although it is associated with ulcerative colitis, a proctocolectomy does not appear to affect biliary disease progression or survival in patients with both ulcerative colitis and PSC.

Orthotopic liver transplantation appears to be the only lifesaving option for patients with progressive hepatic dysfunction from PSC. The survival rate for patients undergoing liver transplantation for PSC is approximately equivalent to that of those undergoing transplantation for other causes of end-stage liver disease, with 5-year survival rates ranging from 75% to 85%. Although the development of cholangiocarcinoma in a PSC liver used to be considered a contraindication to transplantation, some centers have shown excellent survival rates, up to 70% at 5 years, for patients with limited hilar disease who undergo a neoadjuvant protocol of chemotherapy and radiation followed by transplantation.[29] After liver transplantation, 10% to 30% of PSC patients develop recurrent biliary strictures, suggestive of recurrence of disease in the donor liver. Even with the development of strictures, disease progression does not usually follow the aggressive course for which PSC is known. In cases where retransplantation is required, the morbidity and mortality are higher than for primary transplantation.

Recurrent Pyogenic Cholangitis

More common in East Asian populations, recurrent pyogenic cholangitis is caused by cholangiohepatitis or intrahepatic stones. Biliary pathogens such as *Clonorchis sinensis* and *Ascaris lumbricoides* populate the biliary tree. These and other pathogens secrete an enzyme that hydrolyzes water-soluble bilirubin glucuronides to form free bilirubin, which then precipitates to form brown pigment stones. These stones may partially or fully obstruct the biliary tree, causing recurrent episodes of cholangitis and, eventually, abscesses or even cirrhosis. The chronicity of the infection and inflammation places these patients at risk for the development of cholangiocarcinoma. It is unclear whether the primary inciting event is infection causing inflammatory stricture or inflammatory stricture with subsequent infection of stagnant bile.

Recurrent pyogenic cholangitis tends to occur in the third to fourth decade of life, affecting males and females equally. The clinical presentation is that of cholangitis with fever, right upper quadrant pain, and jaundice. Because the infection, inflammation, and stones commonly present in a segmental or lobar pattern, the jaundice tends to be mild. Serum studies are similar to other causes of cholangitis, with a leukocytosis and elevated bilirubin and high ALP levels. Diagnosis is usually made by a combination of CT or MRCP with ERCP (Fig. 88.24). Lobar or segmental atrophy or hypertrophy may be seen in chronic cases.

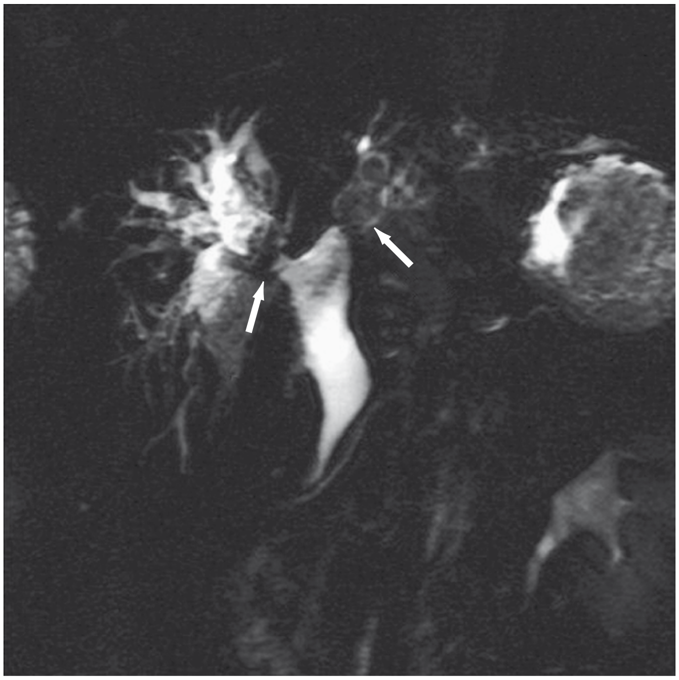

FIGURE 88.24 Magnetic resonance cholangiopancreatography of recurrent pyogenic cholangitis. Intraluminal filling defects from stones are noted in both lobes *(arrows).*

In the setting of an acute attack, conservative treatment with parenteral antibiotics, IV fluids, and analgesics will usually suffice. Failure of this approach, with clinical deterioration, mandates biliary drainage by ERCP or percutaneous methods. Once the attack has subsided, a thorough investigation of biliary tree anatomy will help direct treatment. Definitive operative treatment is almost always required. The goals of surgical therapy are threefold: (1) remove all stones; (2) bypass, enlarge, or resect the strictures; and (3) provide adequate biliary drainage. The variability of presentation and location of disease have spurred the development of a number of operations to achieve these goals. The presence of intrahepatic strictures connotes a complicated case and may warrant resection, strictureplasty, or hepaticojejunostomy. When clearance of all stones is not possible or future need for endoscopic therapy is anticipated, the terminal end of the Roux limb for a hepaticojejunostomy can be brought out as a stoma to provide easy access for choledochoscopy. Given the risk of cholangiocarcinoma, disease affecting predominantly one lobe should be resected in patients with adequate hepatic reserve. In the absence of the development of cholangiocarcinoma, surgical management is highly successful.[30]

Biliary Strictures

Benign strictures can occur anywhere along the intrahepatic or extrahepatic portions of the biliary tree. Intrahepatic strictures are usually a result of cholangiohepatitis and/or ischemic events. Any inflammatory ischemic process along the length of the CBD may cause an extrahepatic stricture. Chronic pancreatitis can cause strictures in the intrapancreatic portion of CBD and are usually long (2–4 cm) with gradually tapered narrowing. Stricturing at the middle portion of the CBD is usually associated with a gallbladder process. The most common reason is iatrogenic and postcholecystectomy, reported in up to 1% of postcholecystectomy patients. Alternatively, Mirizzi syndrome is a large stone in the Hartmann pouch of the gallbladder, compressing the adjacent bile duct and leading to biliary obstruction (Fig. 88.25). These patients often have a cystic duct parallel to the common hepatic duct and an impacted gallstone in the neck or cystic duct. The resultant inflammation can cause a cholecystocholedochal fistula. The treatment of Mirizzi syndrome is cholecystectomy, which may require repair of the common duct; when a large fistula exists, a choledochojejunostomy may be necessary.

Long-standing choledocholithiasis also can cause fibrosis and stricture. ERCP with sphincterotomy, balloon dilation, and stent

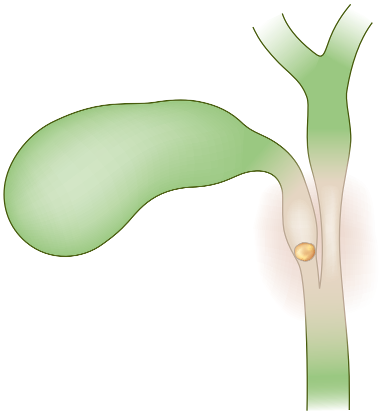

FIGURE 88.25 Mirizzi syndrome. Obstruction of the bile duct from an inflammatory process is the hallmark of this syndrome; the cholecystocholedochal fistula may or may not be apparent.

placement is generally regarded as primary treatment for benign bile duct strictures to make the diagnosis and potentially to treat the process. Endoscopic and percutaneous therapy can provide long-term success in more than 50% of patients. When this is unsuccessful, surgical management with anastomosis of the biliary tree to a Roux-en-Y jejunal limb has success rates of up to 90%.

Biliary Cysts

Choledochal cysts, or biliary cysts, are congenital intrahepatic and/or extrahepatic dilation anomalies. Due to new insights into epithelial markers, and different pathophysiology in different etiologic subtypes, now they are called biliary malformations rather than cysts. They are rare disorders, occurring in less than 1/100,000 patients. They occur more frequently in female patients and in Asian populations. These are considered premalignant conditions and are sometimes diagnosed in infancy; however, they can present in adulthood (Fig. 88.26).[31] Type I choledochal cyst is the most common form and involves only the extrahepatic biliary tree with a fusiform dilation. Type II cysts appear as a saccular diverticulum off the CBD and may be mistaken for an accessory gallbladder. Type III cysts appear as a cystic dilation of the intramural CBD, within the wall of the duodenum, and are also known as choledochoceles. Cysts involving the intrahepatic and extrahepatic biliary tree are known as type IVA, with type IVB as they are multiple cysts limited to the extrahepatic biliary tree. Type V cysts, also known as *Caroli disease,* involve the intrahepatic ducts only. Type V cysts may be solitary but usually occur diffusely in all segments. Although classified as a single disease, there are multiple theories for etiology, but mostly accepted, especially for types I and IV, is the anomalous pancreatobiliary junction (APBJ; Figs. 88.27 and 88.28). With APBJ, the pancreatic duct and biliary tree fuse to form a common channel before passage through the duodenal wall. APBJ is seen in up to 90% of patients with choledochal cysts, but almost exclusively in types I and IV. The fused duct forms a long common channel, which allows pancreatic secretions to reflux into the biliary tree. Because the pancreatic duct has higher secretory pressures than the biliary tree, exocrine pancreatic secretions reflux up into the bile duct and can inflame and damage the biliary epithelium, leading to cystic degeneration. Types II and III almost never present with APBJ and are associated with minimal risk of malignancy.

Presentation. Jaundice is the most consistent symptom, sometimes accompanied with right upper quadrant pain and rarely a palpable mass. Patients may also suffer from nonspecific problems such as weight loss, nausea, and vomiting. Rarely, a long-standing malformation can cause liver injury and even cirrhosis. Diagnostic imaging is the only diagnostic confirmation test. With the current liberal use of CT, the diagnosis of a choledochal cyst is usually suspected on CT but further classified by MRCP or ERCP. Sometimes the distal bile duct is difficult to evaluate by MRCP, so ERCP is more useful for defining the distal biliary tree and pancreaticobiliary junction. Laboratory studies may identify cholestasis and jaundice. In late stages of

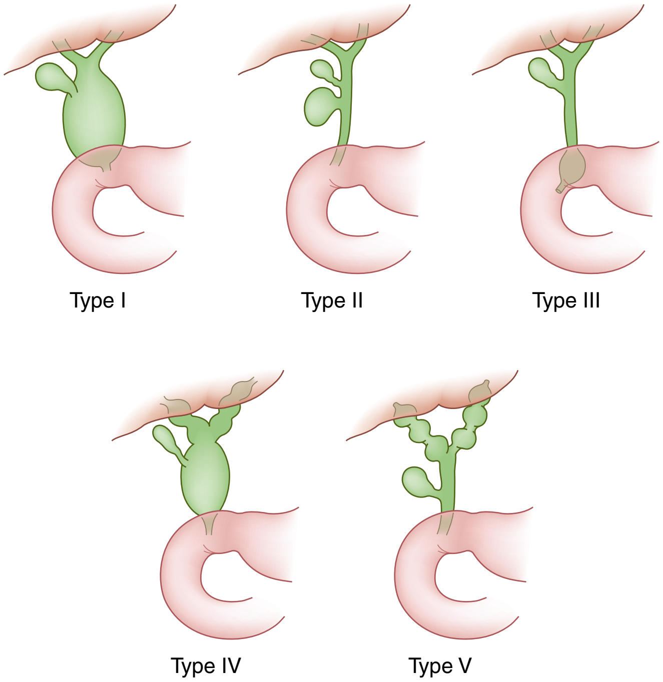

FIGURE 88.26 Choledochal cyst classification.

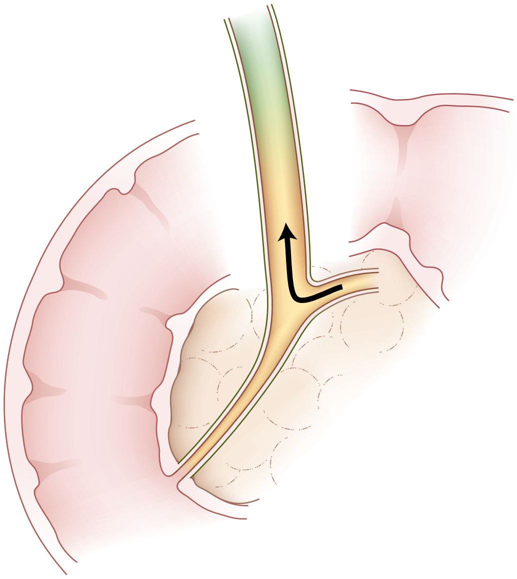

FIGURE 88.27 Anomalous pancreaticobiliary junction. With fusion of the common bile duct and pancreatic duct long before they pass through the duodenal wall, the pancreatic secretions can reflux into the common bile duct and may cause damage to the common duct through pressure or chemical injury.

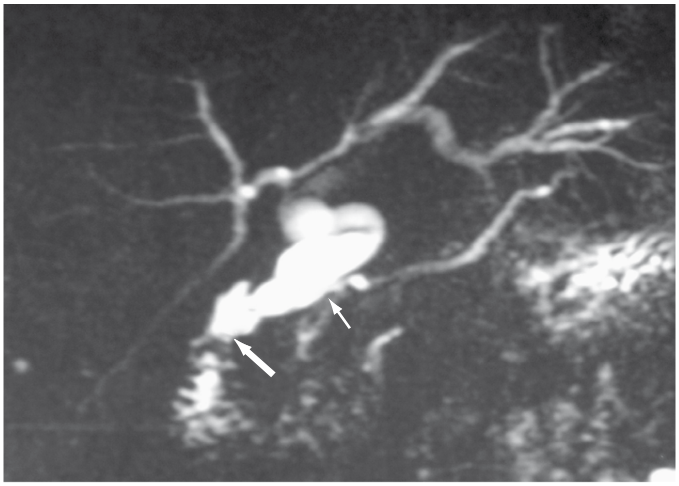

FIGURE 88.28 Magnetic resonance cholangiopancreatography showing anomalous pancreaticobiliary junction with long common channel. The pancreatic duct fuses with the common bile duct *(slender arrow),* and the common channel enters the duodenum *(bold arrow).* Also noted in this illustration is the fusiform dilation of only the extrahepatic bile duct, as seen in a type I choledochal cyst.

disease, secondary hepatic injury and evidence of cirrhosis may be seen. Rarely, first presentation is cholangiocarcinoma. The incident of malignancy ranges between 5% and 30% over a lifetime, most commonly occurring in the seventh decade and almost exclusively occurring in types I *and* IV.[32]

Treatment. Historically, enteric drainage of the cyst was performed without resection, but this approach is complicated by the development of malignancy, recurrent biliary stasis, and infection. Surgical management of choledochal cysts consists of resection of the entire cyst and appropriate surgical reconstruction. Type I cysts are treated by complete surgical excision, cholecystectomy, and Roux-en-Y hepaticojejunostomy. The proximal extent of resection should continue to the nondilated biliary tree and may require anastomosis to the left and right hepatic ducts. The distal duct is oversewn, with care taken not to injure the pancreatic duct. Type II cysts should be excised entirely. Type III cysts are uncommon and may be approached transduodenally. Because the pathogenesis of type III cysts is not clear and almost always does not involve APBJ, endoscopic drainage may suffice. In the setting of duodenal or biliary obstruction, transduodenal excision or sphincteroplasty can be performed. Surgical treatment of type IV cysts must be carefully individualized to the affected anatomy. Type IV cysts affecting only the extrahepatic bile ducts are managed similarly to type I cysts, with excision and hepaticojejunostomy. Those with intrahepatic extension involving only one lobe can be treated with partial hepatectomy and reconstruction. Surgical treatment of Caroli disease ranges from resection if the disease is unilobar to liver transplantation when diffuse disease is detected.

Surgery for Calculous Biliary Disease

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy, first done by Muhe in 1985 (using a direct scope) and later in 1987 by Mouret, is one of the most commonly performed general surgery procedures in the United States. Laparoscopic cholecystectomy has a 0.1% to 0.5% mortality and 2% to 3% morbidity.[33] Laparoscopic surgery results in smaller incisions, less pain, and shorter hospitalization compared with traditional open cholecystectomy, which has significantly increased the number of these procedures done worldwide. Most cholecystectomies are performed for biliary colic, but the operation can be performed safely, and is the gold standard, in the setting of acute cholecystitis. Studies have shown that laparoscopic cholecystectomy for acute cholecystitis may carry longer operative times and a higher conversion rate to the open procedure than when it is performed in the elective setting, with possibly a higher risk of common duct injury. General anesthesia with muscle relaxation is required when a laparoscopic cholecystectomy is performed. Therefore, one contraindication to the procedure is the inability to tolerate general anesthesia. Other contraindications include end-stage liver disease with portal hypertension, precluding safe portal dissection, and coagulopathy. Relative contraindications to surgery include severe chronic obstructive pulmonary disease (poor ability for CO_2 gas exchange), congestive heart failure, and pulmonary hypertension.

The patient is positioned supine with an arm tucked to allow for potential intraoperative cholangiogram, although some prefer both arms out. A Foley catheter may be placed if concerned for prolonged operation or critical illness of the patient. An orogastric tube is placed to decompress the stomach for better view of the upper abdomen intraoperatively. The abdomen and lower chest should be prepped and draped in a manner that can accommodate a retractor system in the event of conversion to an open procedure. The patient should be well secured to the bed to allow for steep reverse Trendelenburg positioning.

Four laparoscopic ports are standard. A 12-mm port at or near the umbilicus is often used for extraction of the gallbladder specimen. The other three ports are 5-mm or even smaller for dissection placed in the right anterior axillary line, right midclavicular line, and subxiphoid location (Fig. 88.29). The lateral port at the anterior axillary line is used to elevate the fundus of the gallbladder toward the right shoulder. This retraction provides exposure to the infundibulum and porta hepatis. The midclavicular trocar is used to grasp the gallbladder infundibulum, retracting it inferolaterally to open the triangle of Calot. Alternative positioning is in the modified French position (split legs), with fundus retraction performed via a subxiphoid port and the 5-mm working ports in the left and right upper quadrants, respectively.

The gallbladder fundus is grasped and retracted cephalad, and the region of the infundibulum retracted laterally to provide exposure for dissection of the cystic structures until a critical view of safety is obtained. A key maneuver is for the surgeon's left operative instrument to distract the infundibulum/Hartmann pouch laterally.[34] The cystic duct and artery are identified by this inferolateral traction of the infundibulum while dissecting free the fibrofatty tissue attaching the infundibulum to the liver. A useful landmark for the cystic artery is the overlying lymph node, known as the Calot node. A high dissection at the infundibulum should be used. If the node of Calot is visible, then limiting the line of peritoneal/serosal division to the upside (gallbladder side) of this structure helps to minimize the risk of CBD injury. With rare exceptions, this lymph node lies immediately on top of the cystic artery. Also, useful to minimize bile duct injury is to obtain a view known as the critical view of safety. Critical view of safety is defined as two and only two structures entering the gallbladder, the lower third of the gallbladder dissected from the liver to expose cystic plate, and a cleared hepatocystic triangle (Fig. 88.30).

Clips are then placed on the cystic artery and duct. The clipped artery and duct are transected between the clips and the gallbladder is

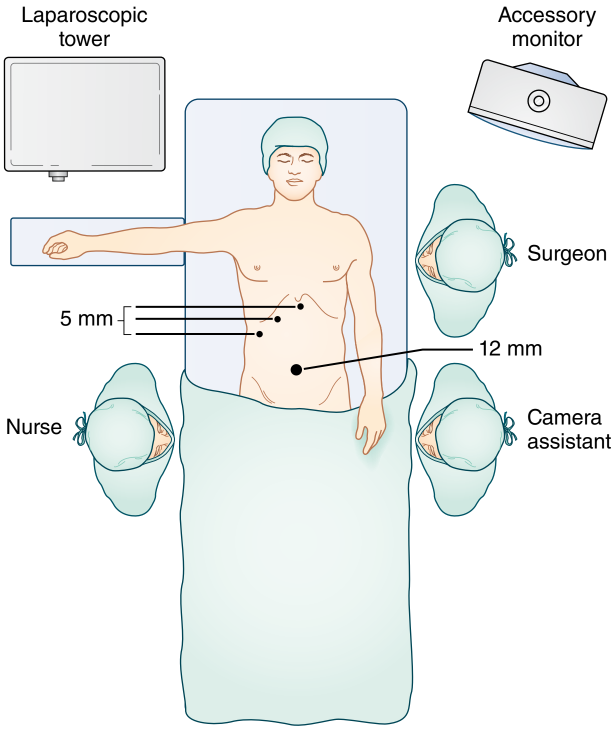

FIGURE 88.29 Laparoscopic cholecystectomy ports. The assistant uses the periumbilical port to provide access for the camera and the most lateral port to elevate the fundus and to expose the neck. The surgeon can then provide inferolateral traction on the infundibulum and open the critical view of safety.

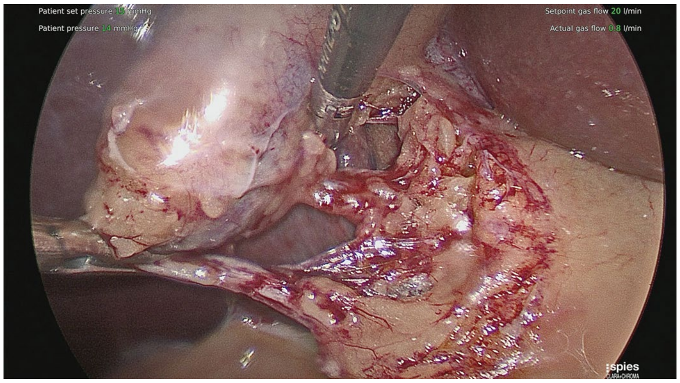

Patient set pressure 15 mmHg
Patient pressure 14 mmHg

dissected off the liver bed using electrocautery. Because the venous drainage of the gallbladder is directly into the liver bed through venules, excellent hemostasis must be achieved during this dissection. The cystic duct and cystic artery clips are inspected just before completion of the dissection of the fundic attachments because the superior traction of the fundus has provided exposure to the porta and triangle of Calot. The gallbladder is then brought out of the abdominal cavity through the umbilical port with the aid of a specimen retrieval bag. Spillage of stones escaping the field must be searched for and retrieved to prevent the development of late perihepatic abscesses.

Intraoperative Cholangiography

Intraoperative cholangiography (IOC) is an essential tool in the armamentarium of the modern surgeon. It was first performed by Dr. Mirizzi in 1932 using plain films and, other than the adoption of live fluoroscopy and change in dye, the technique has remained largely unchanged. A catheter is passed into the cystic duct via a ductotomy and water-soluble contrast is injected to opacify the biliary system (Fig. 88.31). This technique is commonly used to identify choledocholithiasis, help delineate anomalous biliary anatomy, confirm anatomy during a difficult operative dissection, or guide biliary reconstruction.

Intraoperative cholangiography allows CBD stones and injuries to be identified and managed immediately. However, routine cholangiography will identify unsuspected stones in less than 10% of patients, does not decrease the incidence of biliary injury, and can be misinterpreted. Because it adds operative time and fluoroscopic exposure to the operation, many surgeons use intraoperative cholangiography only selectively at the time of cholecystectomy. Although some surgeons still advocate for its use in the academic setting to ensure that trainees are facile in its performance, the Tokyo Guidelines do not encourage the routine use of cholangiography.[33] Indications for the selective use of cholangiography include a diagnosis of gallstone pancreatitis, anomalous or unclear biliary anatomy, and in patients with suspected choledocholithiasis where cholecystectomy is being performed to confirm the diagnosis before ERCP. Familiarity with this procedure is essential for surgeons who wish to manage choledocholithiasis in a one-stage manner with CBDE, which is discussed later this chapter.

Fluorescent Cholangiography

ICG is a water-soluble green dye with spectral absorption at 800 nm. When injected intravenously, ICG binds plasma proteins before being rapidly metabolized by hepatocytes and excreted exclusively into the bile; protein-bound ICG fluoresces green when illuminated with near-infrared (NIR) light and allows for fluorescent cholangiography (FC). The excretion of ICG into the biliary
